# Foreword

IIASA scientists have taken part in a recent effort of the Council of Europe to produce a volume on the future of Europe's population. The alternative scenario approach, which is applied here to the field of population projection, follows up on earlier work of IIASA's Population Project. The IIASA book *Future Demographic Trends in Europe and North America: What Can We Assume Today?* (W. Lutz, Editor, Academic Press, 1991) has provided some of the groundwork for this effort. While that book only gave scenario projections for the regions of Eastern Europe, Western Europe and North America, this chapter in the Council of Europe book gives such scenario projections for a large number of individual countries in Europe.

In its original form the chapter does not include specific tables with the results for individual countries, but rather includes summary tables. Because of frequent demand for the projection results pertaining to individual countries, however, it was decided that an appendix with the country tables should be attached to this reprint of the chapter.

The scenario projections presented here make more extreme assumptions in the high and low values of possible future fertility, mortality and migration levels than are usual in national population projections. Hence this effort should not be seen as competition to national projections, but rather as a scientific contribution to the discussion about possible future population trends and the sensitivity of certain policies (such as pension schemes) to such alternative paths. Future population trends are inherently uncertain. This chapter calculates what happens if they are more uncertain than is usually assumed.

# Alternative Demographic Scenarios for 20 Large Member States of the Council of Europe, 1990-2050

*Christopher Prinz and Wolfgang Lutz*

The following chapter gives alternative population projections for all member countries of the Council of Europe that have a population of more than one million in 1990. Turkey has not been included in this analysis as it is in a demographic sense completely different from all other countries. Neither has Turkey completed the demographic transition, nor is it comparable with respect to migration. The following 20 countries have been considered: Austria, Belgium, Bulgaria, the Czech and Slovak Republic, Denmark, Finland, France, Germany, Greece, Hungary, Ireland, Italy, the Netherlands, Norway, Poland, Portugal, Spain, Sweden, Switzerland and the United Kingdom.

## **5.1. Definition of scenarios**

Table 5.1 lists the scenarios that were defined following the discussions in the preceding chapters on mortality, fertility and migration. In order to keep the size of output and the discussions of results at a manageable scale it was decided to select only nine alternative scenarios out of the essentially unlimited number of combinations between different fertility, mortality and migration assumptions. Even given the restriction to only three different fertility, three mortality and three migration assumptions, a total of 27 scenarios could be defined by cross-classifying these assumptions. When selecting only one-third of the possible combinations the criterion was to choose all extreme combinations (scenarios 1 to 8) plus one average reference assumption (scenario 0). This specific choice results in a systematic permutation of alternative scenario assumptions, a prerequisite for a careful sensitivity analysis. The scenarios are not necessarily realistic, but they mark out the possible range of future demographic trends. Not selecting the extreme combinations would mean to veil possible population developments. The average reference scenario will be and to some extent can be interpreted as the

most likely variant. The idea of the scenario approach, however, is that the user can attach his own probabilities to the given scenarios, depending on the country or countries he is interested in. No probabilities will be assigned to any of the scenarios when discussing some of the most interesting results. Even the average reference scenario will be given equal importance as there is no reasonable justification for that scenario being more likely than the others for all single countries. In the discussion of results, emphasis will be put on one-by-one comparisons, for example what is the impact of one million immigrants annually *versus* no immigration under otherwise identical assumptions?

Table 5.1. *Demographic assumptions of nine scenarios*

Number of scenario	Total Fertility Rate	Life Expectancy male/female	Annual number of immigrants
0	1.7	83.5/89	0.5 million
1	1.3	77/83	zero
2	1.3	77/83	1 million
3	1.3	90/95	zero
4	1.3	90/95	1 million
5	2.1	77/83	zero
6	2.1	77/83	1 million
7	2.1	90/95	zero
8	2.1	90/95	1 million

**Notes:**

Fertility: Reach levels in 2015 (mean length of generation).

Mortality: Low--Increase by 1 year/decade until 77/83 is reached.

Medium--Increase by 2 years/decade until 83.5/89 is reached.

High--Increase by 3 years/decade until 90/95 is reached.

Migration: Reach levels in 2000; between 1990 and 1995, one million immigrants annually. Distribution of immigrants over countries discussed in Chapter 4.

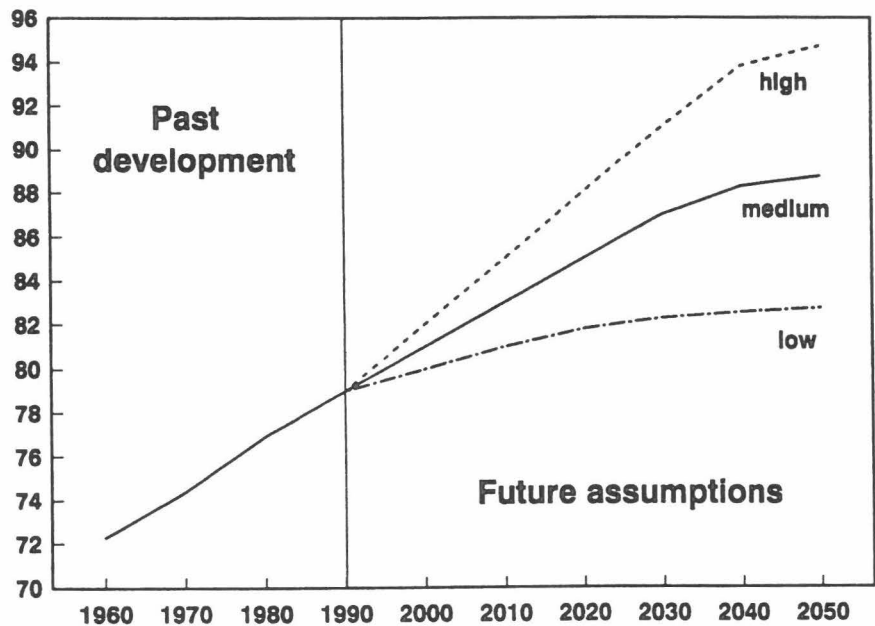

Figures 5.1 and 5.2 below oppose past developments (based on figures presented in Chapters 2 and 3) and future assumptions concerning fertility and mortality, respectively, for all 20 countries together. The Total Fertility Rate (TFR) has declined rapidly from around 2.65 in 1965 to around 1.65 in 1990 (see figure 5.1), while female life expectancy at birth has increased almost linearly from 72 years in 1960 to 79 years in 1990 (see figure 5.2). National trends were less regular, both in the case of fertility and of mortality (see Chapters 2 and 3). Medium fertility assumptions are close to overall fertility levels during the last five years, while the increase in life expectancy assumed for the medium mortality variant is somewhat lower than the increase observed during the last three decades.

Figure 5.1. *Total Fertility Rate of all 20 countries together: past development and assumptions for the future*

Scenarios 1 and 5 combine the low life expectancy assumption with zero immigration but have two very different fertility assumptions, namely a TFR of 1.3 against a replacement level fertility of 2.1. Both are extreme scenarios on the basis of our knowledge but their comparison can tell us about the impact of alternative fertility levels. Scenarios 3 and 7 make a similar comparison possible but under conditions of steeply increasing life expectancy. Hence a comparison of the differences between scenarios 1 and 5 on the one hand and 3 and 7 on the other hand shows the impact of alternative mortality levels on the fertility effect. This last question refers to a second-order impact analysis.

Figure 5.2. *Female life expectancy, all 20 countries together: past development and assumptions for the future*

A comparison between scenarios 3 and 4 allows the assessment of strong immigration under the conditions of very low fertility and mortality, that is, a situation of extreme ageing. Comparing scenario 4 to scenario 8 indicates the difference high fertility would make under strong immigration and low mortality conditions. Comparing scenarios 5 and 6, again, shows the impact of high immigration under high fertility and mortality conditions.

If one is interested in the consequences of alternative assumed mortality conditions under otherwise identical circumstances, a comparison of scenarios 1 and 3 will give this information for the case of no immigration and low fertility, and a comparison of scenarios 5 and 7 for the case of no immigration and high fertility. Again, comparing differences between scenarios 1 and 3 on the one hand and scenarios 5 and 7 on the other hand gives a second-order impact analysis of alternative fertility levels on the mortality effect. Comparing scenarios 2 and 4, and scenarios 6 and 8 will give the same information under assumed high immigration.

A comparison between scenarios 1 and 4 will show the combined effect of strong immigration and increasing life expectancy under low fertility conditions. There are several other cases worth studying in which one variable remains unchanged, that is when the combined effect of two changes is given. Scenario 0, the reference scenario, generally provides a kind of average trend to be compared to possible extreme developments.

In all cases a convergence of fertility and mortality levels among the 20 countries is assumed, supported by the demographic trends of the past decades and the development towards a European union. Concerning fertility it is assumed that all countries reach the specified level by the year 2015 which corresponds roughly to the mean length of a generation. For the period between 1990 and 2015 fertility levels are interpolated. The rationale for this assumption which implies a convergence in presently different fertility levels is given in Chapter 2 above. For mortality, a different mode of convergence has been assumed. In the low case, life expectancy for men and women increases by 1 year during a decade until the level of 77/83 years is reached. In the medium case, it increases by 2 years per decade until 83.5/89 years is reached, and in the high case it increases by 3 years per decade until 90/95 years is reached. Depending on the mortality level in 1990, in some countries the target values are not reached within the projection period. Again, the rationale for these assumptions which imply

identical speeds of improvement for countries presently at different levels is given in Chapter 3 above. For Bulgaria, the CSFR, Hungary, and Poland a smoother ten-year mortality transition period was assumed with half the improvement in each of the three cases. Assuming convergence in fertility and mortality levels implies that country-specific projections will be biased in the short run, i.e. for the next 10 to 15 years. According to our assumptions, some countries would experience an unexpected jump upwards or downwards (be it in fertility or mortality) during the coming decade. Consequently, in the short run country specific projections cannot be directly compared to national forecasts, but neither projection results for all countries together nor long-term country-specific projections are affected by this assumption on convergence in levels.

While, both in the case of fertility and of mortality, levels have been assumed to converge, age differentials were kept constant in each country. Concerning mortality, a reasonable age pattern needs to be assumed freely by the modeler in any case, as no model mortality life tables for a life expectancy at birth equal to 95 years exist. In the case of fertility, a level corresponding to a TFR equal to say 1.3 may be obtained by quite different age-specific rates. There is, however, hardly any consequence on the results of population projections as long as the size of subsequent cohorts is reasonably stable. It is the number of births that matters, but not the relative distribution over ages of mothers.

In the case of immigration the stated level is assumed to be reached by the turn of the century. During the period 1990-1995, one million immigrants annually are assumed. The distribution of immigrants over the individual countries results from a complex weighing procedure which considers both population size and the level of recent immigration. This procedure is discussed in more detail in Chapter 4 above. Some assumptions have to be mentioned. Firstly, since immigration is equal to net migration, it is assumed that in the case of zero immigration (scenarios 1, 3, 5 and 7) at each age immigration = emigration = net migration = zero. While this may be wrong in reality, as we should expect immigration at some age groups, and emigration at some other age groups, this simplification is defensible in a long-term projection model. Secondly, the proportional distribution of immigrants over the 20 countries is kept constant, although it may be possible that — due to economic development and to the nearness of the Mediterranean countries — in particular some southern and eastern European countries will have a larger share in the future. Thirdly, all non-east European Council of Europe countries are assumed to be net immigration

countries in the future, while for example Ireland has been a net emigration country for most of its past. But even Ireland could become an immigration country in the future, as can be seen from the 1970s. Fourthly, formerly eastern European countries have not been considered net immigration countries. Due to the uncertain economic situation, Bulgaria, the CSFR, Hungary and Poland have been assigned zero net migration, a simplification that again seems defensible in the long run.

### 5.2. Population size and growth

Figure 5.3 plots the total population sizes for all 20 countries together from 1990 to 2050 under the nine scenarios defined above. All the aggregate information discussed in the following has been derived by summation of individual country results.

Figure 5.3. Total population size of all 20 countries together

As expected, the graph gives the picture of an opening trumpet with variation increasing over time. Scenario 1 with the lowest fertility and life expectancy assumptions and no immigration will result in a significant decline in the total population size especially after 2010, from 450 million people in 1990 to only 340 million in 2050. Up to the year 2010 there will be little if no decline, which is due to age structural effects and the step-by-step approach of the assumed low TFR, while the decline clearly gains momentum thereafter.

Table 5.2. *Population size in millions, 1990 and 2050 by scenario*

Country	Size in 1990	Projected size in 2050		
		Scen.0	Scen.1	Scen.8
All countries	448.9	467.7	342.1	605.6
Austria	7.6	7.6	5.4	10.1
Belgium	9.9	9.7	7.1	12.8
Bulgaria	9.0	8.0	6.3	9.9
Czechoslovakia	15.7	15.8	12.5	19.5
Denmark	5.1	5.1	3.7	6.6
Finland	5.0	5.1	3.8	6.5
France	56.7	65.2	47.6	84.5
Germany	78.0	78.8	53.8	106.7
Greece	10.2	10.5	7.5	13.7
Hungary	10.6	9.0	7.0	11.1
Ireland	3.7	5.2	4.0	6.5
Italy	57.7	55.9	40.4	73.0
Netherlands	14.9	16.4	11.7	21.5
Norway	4.2	4.8	3.5	6.3
Poland	38.4	41.3	32.8	50.6
Portugal	9.9	11.6	8.4	15.2
Spain	39.3	39.4	29.6	49.9
Sweden	8.5	9.4	6.7	12.4
Switzerland	6.6	7.4	4.9	10.2
United Kingdom	57.3	61.3	45.4	78.5

Effects of this rather extreme population decline scenario will be quite different for individual countries. This can be seen from Table 5.2 above which gives the population size of each country and of all countries together, for 1990 and for 2050 according to the reference scenario 0 and the two extreme scenarios with respect to total population size (scenarios 1 and 8).

Under the low population size scenario 1, Italy, which is presently still slightly larger than France, would decline from 57.7 million to 40.4 million by 2050 while France would only decline to 47.6 million. Under this scenario, Germany would also decline by more than 24 million, while Hungary would lose one-third of its present population over the next 60 years. The other extreme is Ireland: due to its extremely young population structure the total population size would even under this extreme assumption, increase until 2020 and be 8% above the 1990 value in 2050.

The second lowest population sizes result from scenarios that differ from scenario 1 only with respect to one variable, mortality or migration (see Figure 5.3): scenario 3, assuming significant improvements in mortality, and scenario 2, assuming one million immigrants annually. As compared to scenario 1 both scenarios will result in a visibly greater number of inhabitants by the year 2050: 56 million in the case of high life expectancy, and 64 million in the case of high immigration.

There is another group of three scenarios which are very similar to each other in terms of total population sizes although they will be different in terms of age structural characteristics. Scenarios 0, 4 and 5 all result in total population sizes slightly below 470 million by the middle of the next century which reflects a population increase of about 5% over the next 60 years. These scenarios are based on very different assumptions. Scenario 0 assumes medium fertility, mortality and migration, scenario 4 combines low fertility and mortality with high immigration, while scenario 5 combines high fertility and mortality with zero immigration. Hence we can conclude that with respect to population size the high fertility assumption of scenario 5 is compensated by the high immigration and high life expectancy assumptions of scenario 4. And both combinations of assumptions give population sizes close to that of the reference scenario.

While under this reference scenario total population size of all 20 countries together is, by 2050, some percentage points higher than in 1990, some of the

individual countries will grow considerably (Ireland +40%, Norway and France +15%) and others will shrink (Hungary -15%, Bulgaria -11%, Italy -3%, compare Table 5.2).

Clearly the highest population size at each point in time will result from scenario 8 which combines high fertility with high life expectancy and high immigration. This is interesting to note because this scenario might be considered not unlikely in terms of the fertility, mortality and migration assumptions involved. According to this scenario the population size of the 20 countries would reach 600 million by the year 2050, or increase by 35% by the middle of the next century. Low life expectancy (scenario 6) or alternatively zero immigration (scenario 7) reduces total population size of scenario 8 to 545 and 525 million, respectively, by the year 2050. Effects of the extreme population increase in scenario 8 will again be quite different for individual countries. Bulgaria and Hungary, both with zero immigration, that is scenario 8 equals scenario 7, will only grow by 5-10%. Countries like Italy or Spain will experience a 27% increase until 2050, while countries like France, Norway and Switzerland will grow by around 50%. The extreme is again Ireland with an increase of 75% by 2050, while Poland will grow by 32% even without immigration.

A comparison of zero and high immigration scenarios under otherwise identical assumptions (e.g. scenario 1 *versus* 2, scenario 3 *versus* 4, etc.) shows that in the long run, by 2050, immigration adds around 65 million people in the case of low fertility and around 80 million in the case of replacement fertility. Comparing high and low life expectancy assumptions (e.g. scenario 1 *versus* 3, scenario 5 *versus* 7, etc.) shows the long-term impact of a strong mortality decline on population size: overall it is around 58 million by 2050. Finally, comparing low and high fertility scenarios, again under otherwise identical assumptions (e.g. scenario 1 *versus* 5, scenario 2 *versus* 6, etc.), shows that by 2050 high fertility adds 125 million people without immigration and even 140 million in the case of high immigration.

Figure 5.4 gives the annual rates of natural increase for all countries together resulting from the different scenarios. Natural increase results only from the difference between births and deaths and does not reflect migration. In contrast to Figure 5.3 which shows increases and decreases, Figure 5.4 only gives decreasing curves, at least after 2015. Values above zero indicate that the popula-

tion will experience natural growth; values below zero indicate less births than deaths, that is, a shrinking of population size unless immigration compensates for it.

Figure 5.4. Average annual rate of natural increase of all 20 countries together (in %)

It is interesting to note that over the next 10 years all scenarios result in a positive natural increase of the western European population. Despite universal sub-replacement fertility this is due to the age structure and to some extent to declining mortality. It is also interesting to note that by the middle of the next century all scenarios except scenario 8 will result in negative or at least zero natural increase. The fact that this happens even under replacement fertility is again a consequence of the age structure, in a way the negative momentum of population growth resulting from the presently low fertility. Scenario 1 which

assumes low fertility, low life expectancy and no immigration will even result in an annual rate of decrease of 1.3% per year by the middle of the next century with the tendency to further increase the speed of shrinking. Once the process of shrinking has gained such momentum, its possible reversal would take a considerable amount of time. Although immigrants are not counted in contributing to natural increase, the children of immigrants are counted and hence make a difference on natural increase which is shown by comparisons between scenarios with zero and high immigration under otherwise identical assumptions.

### **5.3. Children and working age population**

Figure 5.5 gives the proportion of children aged 0-19 in the total population of all countries taken together. As could be expected, the number of children shows the greatest sensitivity to scenario assumptions concerning fertility. From 5.5 million for all countries in 1990, with low fertility (1.3 children per woman) the annual number of births would decline to only 2 million by 2050 with zero migration and to 2.75 million with high immigration. With replacement fertility, however, the annual number of births would remain stable even without immigration or increase to more than 7 million by 2050 with high immigration (see appendix tables).

The proportion of children in the population varies by a factor of two between the highest and the lowest scenario. The fact that the increase in variation is not evenly spread over time follows from the assumption that assumed fertility levels will be reached step by step and only remain constant after 2015. This can be readily seen in the figure.

Concerning the proportion of children, which was around 26% in 1990, the scenarios fall into three groups, although in the long run the differences within those groups are remarkable. The lowest proportions of children — in the extreme case of scenario 3, low fertility and mortality and zero migration, the proportion is cut into half — result from scenarios 1 to 4, which all assume a fertility level of 1.3. The second group includes only scenario 0 that has the intermediate TFR of 1.7. The third and highest group — with a constant proportion in the extreme case of scenario 6, high fertility, mortality and immigration — finally consists of scenarios 5 to 8 which assume replacement level fertility. The absolute numbers of children within these three groups vary

less than the proportions shown in the figure because the proportions are also influenced by the numbers of elderly which are subject to the mortality and immigration assumptions.

Figure 5.5. *Proportion of children aged 0-19 in total population, all 20 countries together*

It is probably the most remarkable finding of the scenario exercise that the proportion of the population of working age is relatively insensitive to the widely differing assumptions on future fertility, mortality and migration. Figure 5.6 shows that over the next 20 years Europe can count on a relatively stable share of men and women of working age, that is, age groups 20 to 59: around 55% of the population no matter what scenario is being considered. Thereafter, there will be 25 years of significant and almost inevitable decline of proportions in working age. This decline will on average amount to about 10 percentage points. After 2040, most scenarios show a relatively stable situation with between 43% and

49% of the population of working age. Up to 2020 the difference between the lowest scenario 7, assuming high fertility and life expectancy and zero migration, and the highest scenario 2, with the opposite assumptions, will never be more than 5 percentage points.

Figure 5.6. *Proportion of the population in the economically active age-groups 20-59, all 20 countries together*

The proportion of the population of working age mainly depends on the assumptions on mortality and thus on the proportion of elderly. The question of whether one million people enter Europe annually or not does not seem to make all that much difference on the proportion of the population of working age, while it makes a big difference to the size of that group. Only high immigration together with replacement fertility would result in a stable, or in fact steadily increasing, population of working age. Neither immigration nor high fertility alone would prevent the working age population from shrinking in size.

Table 5.3. Changes in the size of the working age population, by country

Percentage change, 1990-2050	Assumptions concerning fertility/migration		
	Scenario 0 (medium)	Scenario 3 (low)	Scenario 8 (high)
20% or more	Ireland		Ireland Norway Sweden France Portugal Switzerland
10% to 20%		Ireland	Poland United Kingdom Netherlands
0% to 10%	Norway France Sweden		CSFR Greece Germany Austria Belgium Denmark Finland
-10% to 0%	Poland Portugal CSFR United Kingdom		Spain Italy Bulgaria Hungary
-20% to -10%	Switzerland Netherlands Greece Finland Denmark Austria Belgium Spain	Poland CSFR	
-30% to -20%	Bulgaria Germany Italy Hungary	Norway France Sweden United Kingdom Portugal	
-40% to -30%		Bulgaria Hungary Netherlands Finland Denmark Spain Belgium Greece Switzerland	
-40% or less		Austria Italy Germany	

In the long run the working age population would decline by around 16% with high immigration and low fertility, by around 12% with high fertility and zero migration, and by around 13.5% with intermediate fertility and immigration.

Changes in the size of the working age population will again be quite different for individual countries. Table 5.3 above groups the countries according to the percentage change in the size of the population aged 20-59 years during the period 1990-2050.

Three scenarios were selected: scenario 0, using medium reference assumptions, scenario 3, assuming low fertility and mortality and zero migration resulting in the lowest size of the working age population, and scenario 8, assuming high fertility and immigration and low mortality thus resulting in the largest size of the working age population.

Ireland has an outstanding position among European countries with a significantly increasing working age population under any scenario, including scenario 3. Some countries, in particular the central European countries Austria, Germany, and Switzerland, can be found in quite different places in the sequence of the 20 countries listed in Table 5.3. On the one hand, these countries have had low fertility for a long time already, and on the other hand immigration is relatively high. As a consequence, in those countries high immigration scenarios have a remarkable positive impact on the size of the working age population.

#### **5.4. Ageing of the population**

During the following three decades ageing depends relatively little on the assumptions adopted. Figure 5.7 gives the proportion of elderly people aged 60 years and over in the total population of all countries taken together. From less than 20% in 1990, the proportion of elderly will increase up to 25-30% until 2020. Thereafter, ageing strongly depends on the scenario assumptions considered. With high fertility and low life expectancy (scenarios 5 and 6), the further increase in the proportion of elderly is limited to a few percentage points; the proportion will even decline somewhat after 2035. With low fertility and high life expectancy, extreme ageing is prolonged: almost 47% of the population aged 60 years and over by 2050 with zero migration assumptions. Under these

assumptions, even high immigration of 1 million people per year would only delay the ageing process some 10 years.

Figure 5.7. *Proportion of the population above age 60 for all 20 countries together*

Comparing variables one by one, that is, high *versus* low fertility, high *versus* low mortality, and high *versus* no immigration — under otherwise identical assumptions — shows the impact of those variables on the ageing process. High immigration lowers the percentage of elderly by 3-5 percentage points, while low fertility and high life expectancy accelerate the increase in the proportion of elderly by 8-11 and 6-8 percentage points, respectively.

Ageing becomes even more dramatic when we look at the oldest old, the population aged 80 years and over. From around 14 million in 1990, this group of the

population will grow almost threefold, if low life expectancy is assumed, and almost sixfold under high life expectancy assumptions. For these conclusions, fertility and migration assumptions are irrelevant. In scenario 3, this gives 20% of the total population by 2050, compared to 3.2% in 1990. The increase in the number of people aged 80 years and over is considerably larger among men than among women, while the proportion is always larger among women. The proportion of the oldest old in the total population is given in Figure 5.8. Even under favourable demographic assumptions (scenarios 5 and 6, both assuming high fertility and low life expectancy) this proportion will grow significantly in the long run. In the worst case of low fertility and high life expectancy, however, the proportion would increase by a factor of 6, or by a factor of around 8 among men and a factor of around 5 among women.

Figure 5.8. *Proportion of the population above age 80 for all 20 countries together*

Proportions of the oldest old among the elderly are given in the appendix tables. Both the observed proportion in 1990 and the projected changes in the proportion are comparable to the proportion of elderly among the total population. The main difference is that up until the end of the projection period the proportion of the oldest old among the elderly is independent of assumptions on fertility. With high life expectancy assumptions, the proportion would increase exponentially from 16.6% in 1990 to around 42% by 2050, while it would still increase rapidly to some 28% by 2050 under low life expectancy assumptions. With 36% of the elderly by 2050 the future proportion of the oldest old is in between the two extremes with medium life expectancy assumptions. Independent of the assumptions the increase is clearly strongest during the period 2040-2050.

The mean age of the population is another useful indicator of ageing. More than the proportion of elderly, the mean age is also influenced by assumptions on both fertility and migration. Figure 5.9 presents mean ages of all countries taken together.

Figure 5.9. Mean age of the population for all 20 countries together (in years)

Mean ages increase considerably under all scenarios. Even with average assumptions of the reference scenario 0, mean ages increase by not less than 10 years within our projection period, from 35.7 to 45.6 among men and from 39.0 to 48.7 among women. Without any immigration, high fertility and low life expectancy (scenario 5) lead to a more moderate increase by only 5 years until the year 2030, when the mean ages stabilize. Low fertility and high life expectancy (scenario 3), on the other hand, result in an almost linear increase by 17 years by the year 2050, with no sign of change in the trend to increase further. High immigration generally reduces the increase in the mean age by two to three years in the long run. The population under low fertility and low life expectancy (scenarios 1 and 2) assumptions is some three to four years older than under high fertility and high life expectancy (scenarios 7 and 8), which indicates that our low fertility assumption has a stronger impact on ageing — measured in terms of mean ages — than our high life expectancy assumption.

Mostly depending on the level of ageing already reached by today, future ageing of the population will also be quite different for individual countries. Table 5.4 groups the countries according to the change in the mean age of the population (in years) projected for the period 1990-2020. The two extreme scenarios with respect to ageing, the low fertility, low mortality and zero migration scenario 3, and the high fertility, high mortality and high immigration scenario 6, were depicted for illustration. This table also includes the mean ages of all countries in 2020 in order to be able to compare the speed of ageing with the level of ageing reached by 2020.

Independent of our scenario assumptions, the Netherlands and Spain are the two countries that can expect the most pronounced increase in mean ages (more than 9 years under scenario 3); a consequence of the fact that these two countries have experienced the most rapid fertility decline among all European countries. On the other side of the spectrum we find Sweden, the country with the oldest population in 1990, which will age the least among all the 20 countries (less than 1 year under scenario 6). The highest levels of mean ages are reached in Italy, in Germany and in Switzerland (almost 49 years for females under scenario 3), by far the lowest levels in Ireland (35 years for males under scenario 6).

Table 5.4. Mean ages of the population, by country: changes between 1990 and 2020 and respective level in 2020

Increase in mean ages, 1990-2020	Assumptions fertility/mortality/migration	
	Scenario 3 (low)	Scenario 6 (high)
9 years or more	Spain	47.3
	Netherlands	47.2
7.5 to 9 years	Italy	48.5
	Greece	47.6
	Portugal	46.0
	Switzerland	48.8
	Ireland	40.7
	Finland	47.3
	Poland	42.8
6 to 7.5 years	France	46.0
	Belgium	47.5
	Denmark	47.4
	Austria	47.7
	Germany	48.9
	CSFR	43.4
	Bulgaria	44.8
	Norway	45.7
	United Kingdom	45.8
	Hungary	45.2
4.5 to 6 years	Sweden	47.0
	Spain	42.8
3 to 4.5 years	Netherlands	42.4
	Ireland	36.8
	Italy	43.5
	Poland	39.2
	Greece	42.6
	Portugal	41.1
	Finland	42.6
	CSFR	39.7
1.5 to 3 years	France	41.3
	Denmark	42.7
	Bulgaria	40.9
	Belgium	42.6
	Switzerland	43.1
	Hungary	41.4
	Austria	42.5
	Norway	41.0
	United Kingdom	41.2
	1.5 years or less	Germany
Sweden		42.0

Interesting conclusions are obtained by comparing differences between scenarios in both total population size and population structure (in terms of mean age of the population). As already mentioned, scenarios 0, 4 and 5 result in around 465 million people by the middle of the next century by combining very different fertility, mortality and migration levels. With high fertility, low life expectancy and no migration (scenario 5), the population is some 5 years younger as compared to reference scenario 0. With the opposite assumptions of low fertility, high life expectancy and high immigration (scenario 4), it is some 5 years older. Or, as another example, scenarios 1 and 4, both assuming the low fertility level of 1.3, give almost identical increases in mean ages of the population by some 13-14 years until 2050, the former assuming low life expectancy and no immigration, the latter assuming high life expectancy and high immigration. While these two opposing assumptions compensate each other with respect to the age structure, scenario 4 gives a total population size of 465 million by 2050, which is 40% higher than the projected population size under scenario 1.

In this chapter, we have only presented numerical results of our population projections. The following chapter will attempt to arrive at relevant interpretations and conclusions.

### **Appendix. Additional results**

The above-given survey of results of nine alternative scenario calculations for the period 1990 to 2050 for 20 large member countries of the Council of Europe has largely focused on aggregate results based on the summation of national results. The following appendix tables give additional results on a country-by-country basis. For selected points in time, some of the most important demographic indicators are listed scenario by scenario. Assumptions for the nine scenarios on fertility, mortality and migration are indicated in the heading of the tables. For details the reader is referred to the definition of scenarios in section 5.1.

Tables on computer diskettes and more detailed results can, on request, be obtained from IIASA, A-2361 Laxenburg, Austria.
