IIASA STUDIES IN ADAPTIVE DYNAMICS   NO. 121

EEP

The Evolution and Ecology Program at IIASA fosters the development of new mathematical and conceptual techniques for understanding the evolution of complex adaptive systems.

Focusing on these long-term implications of adaptive processes in systems of limited growth, the Evolution and Ecology Program brings together scientists and institutions from around the world with IIASA acting as the central node.

Scientific progress within the network is collected in the IIASA Studies in Adaptive Dynamics series.

Abstract

We use an individual-based eco-genetic model to examine the demographic and evolutionary consequences of selective mortality on a species with parental care, the smallmouth bass *Micropterus dolomieu*. Our analyses are grounded in a long-term (1936-2003) empirical study of the dynamics of two populations that differ widely in both density and life history. The model we construct extends previous approaches by including phenotypic plasticity in the age and size at maturation, by permitting density-dependent somatic growth, and by analyzing how costs associated with parental care alter model predictions. We show that, first, additional mortality on age-0 individuals applied for 100 years causes reduced population abundance and biomass, faster somatic growth rates, and phenotypic plasticity toward slightly larger sizes at maturation. Second, mortality on individuals above a minimum size limit, also applied for 100 years, has a small influence on population abundance and somatic growth, causes a reduction of biomass, as well as substantial evolution of the probabilistic maturation reaction norm leading to younger ages and smaller sizes at maturation. Third, the incorporation of body-size-dependent survival costs associated with parental care (i.e., by reducing the number of small breeding adults at high population densities, increasing the mortality of parents that breed at small body sizes, or increasing the mortality of offspring originating from small-sized parents), reduces the amount of evolution predicted to occur within 100 years. Together, these results underscore that selective harvest can cause both phenotypically plastic responses and rapid evolution, however, the rate and magnitude of the evolved changes are sensitive to a species' life history characteristics.

Keywords: probabilistic maturation reaction norm; harvest; evolution; phenotypic plasticity; life history; density-dependent growth; eco-genetic model; fishing-induced adaptive change; parental care; individual-based model; species introduction.

Introduction

To understand the effects of selective mortality on a population, it is critical to distinguish between plastic and evolutionary responses in key life history traits such as age and size at maturation (Reznick 1993; Rijnsdorp 1993). Selective mortality can induce rapid evolutionary changes in age and/or size at maturation (e.g., Reznick et al. 1990; Haugen and Vøllestad 2001) by favoring those individuals that reach maturity while minimizing their exposure to mortality (Law 2000). Selective mortality can also cause a phenotypically plastic response in age and size at maturation by altering environmental conditions for somatic growth through effects on population density and food availability (Law 2000; Hutchings 2004; Reznick and Ghalambor 2005; Dunlop et al. 2005b). Disentangling genetic and plastic responses is of particular significance to resource managers because genetic responses might take much longer to reverse than mere plastic changes (Law 2000). In the wild, however, it can be difficult to rule out the influence of confounding variables and to collect the data necessary for distinguishing between plastic and genetic responses. Models are therefore indispensable for predicting and understanding the consequences of selective mortality because they enable full control of any extraneous variables and salient assumptions.

In this study, we develop and analyze a model of mortality-induced evolution and parameterize it for a species with parental care, the smallmouth bass *Micropterus dolomieu*. We take a step beyond previous models of mortality-induced evolution (e.g., Law 1979; Abrams and Rowe 1996; Heino 1998; Martinez-Garmendia 1998; Ratner and Lande 2001) by permitting phenotypic plasticity in both the age and size at maturation, by allowing somatic growth to be density-dependent, and by including costs associated with parental care. This approach permits a more realistic framework in which to predict both the rate of evolutionary change and its

endpoint. We include phenotypic plasticity in our study by modeling maturation reaction norms (MRNs). A MRN predicts the phenotypically plastic response of age and size at maturation to environmental variation in somatic growth rate (e.g., Stearns and Koella 1986; Roff 1992; Ernande et al. 2004). Plastic changes in response to environmental variation in somatic growth will cause the realized combination of age and size at maturation to be shifted along the MRN, whereas selection is expected to force an evolutionary shift of the entire MRN away from its original position (Heino et al. 2002). Using this approach, studies of maturation in several marine fish stocks have demonstrated consistent correlations between high levels of harvest mortality and shifts in MRN position (Grift et al. 2003; Barot et al. 2004b; Olsen et al. 2004, 2005).

Despite the growing number of studies examining fishing-induced evolution (e.g., Baskett et al. 2005; Olsen et al. 2005; Reznick and Ghalambor 2005), it is not fully known how a species' life history characteristics influence the rate of the evolutionary response to selective mortality. Parental care is one important aspect of life history that is present in numerous fish species (Mank et al. 2005) and yet its influence on the response to selective mortality has received little, if any, attention. While parental care can improve offspring survival, such care can obviously be costly, by demanding a large expenditure of energy and by increasing a parent's exposure to predators (Clutton-Brock 1991). If sufficiently severe, these costs imply selective forces that might alter a population's predicted evolutionary response to mortality.

The focal species of our study, the smallmouth bass, shows paternal care in the form of an extended nest-guarding period that can last up to six weeks in the spring, during which the male parent fans the eggs to prevent fungal infection and defends the brood from potential predators (Ridgway 1988, 1989). The male feeds at a much diminished rate during the nest-guarding period (Ridgway and Shuter 1994), relying on stored energy reserves for sustenance (Mackereth et al. 1999). Evidence suggests that the presence of parental care in smallmouth bass is altering

the selective forces acting on parental body size through three mechanisms. First, small males are disadvantaged because they emerge from winter with proportionately lower weight-specific energy reserves than larger males (Mackereth et al. 1999) and experience higher weight-specific maintenance costs (Shuter and Post 1990). Consequently, small males possess insufficient energy reserves for maintaining adult home ranges and for nest guarding when population density is high and food availability low (Ridgway et al. 2002). Therefore, small males might not initiate spawning even when they are mature, which could explain why the fraction of mature males that form a nest decreases with increasing population density (Ridgway et al. 2002). Second, smaller males might suffer higher over-winter mortality because their reserves are further depleted after the energetically demanding nest-guarding period (Shuter et al. 1980; Mackereth et al. 1999). Third, smaller males might be less effective at protecting their brood from predators and, accordingly, their offspring might suffer higher mortality (Ridgway and Friesen 1992; Wiegmann and Baylis 1995; Knotek and Orth 1998). The selective pressures resulting from the above three mechanisms favor the evolution of larger body sizes at maturation and might thus directly oppose those resulting from size-selective mortality on larger individuals, which, if acting alone, would favor maturation at smaller body sizes.

Two well-studied populations of smallmouth bass provide the empirical basis for assessing the usefulness of our modeling approach. The two study populations, one from Provoking Lake and the other from Opeongo Lake (Algonquin Provincial Park, Canada, 45°42'N, 78°22'W), were introduced from a common source in the early 1900s. The Opeongo Lake population has been studied continuously since 1936 and the Provoking Lake population has been studied periodically from the late 1940s. Since their original introduction, these two populations have diverged, with Provoking Lake now supporting a population with a higher density, slower somatic growth rates, and smaller sizes at maturation relative to the Opeongo Lake population

(Dunlop et al. 2005a). Empirical evidence suggests that the lower rates of predation on age-0 smallmouth bass in Provoking Lake, resulting from the depauperate fish community, might have contributed to the higher population density and slower somatic growth rates in that population (Dunlop et al. 2005a). Empirical evidence also indicates that, despite the existence of higher levels of mortality on the large size classes in Provoking Lake (Dunlop et al. 2005a), the two populations exhibit similar maturation reaction norms (Dunlop et al. 2005b). We will use our model to assess how the costs of parental care might be affecting the rates of maturation reaction norm evolution in these populations and whether it is reasonable to expect detectable changes in the maturation reaction norm after only 100 years of life in the different selective environments of Provoking Lake and Opeongo Lake.

In this study, we introduce an individual-based model that aims at incorporating the salient ecological processes underlying mortality-induced evolution. Throughout this study, we use the term 'eco-genetic' to characterize this model because it predicts the rates at which quantitative genetic traits evolve while at the same time integrating key aspects of the ecological setting (e.g., age and size structure, density-dependent growth, and phenotypic plasticity) into the selective environment that determines those rates. On this basis, we model the introduction of a smallmouth bass population into environments with differing levels of age-0 mortality or size-selective mortality and observe the implications of these differences for population dynamics, somatic growth, and maturation reaction norm evolution. We then incorporate the three possible body-size-related effects of parental care discussed above and determine how these additions alter predicted changes in demography and predicted rates of maturation reaction norm evolution. The detailed empirical data available for the Provoking Lake and Opeongo Lake populations provide a realistic context in which to evaluate these predictions and assess the possible role of parental care in determining how these populations have diverged since their introduction.

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

Methods

An individual-based eco-genetic model was constructed to study the introduction of a smallmouth bass population into an environment with selective mortality. In accordance with the historical timeframe of the smallmouth bass introductions into Opeongo Lake and Provoking Lake, the eco-genetic model described below was run for 100 years in discrete, one-year time steps.

Data sources

Data from the Provoking Lake and Opeongo Lake smallmouth bass populations were used to parameterize the model. Empirical data have been collected on the Opeongo Lake population since its introduction in the early 1900s via an access point creel survey (Shuter et al. 1987). These creel data include temporal estimates of growth, population density, and mortality, corrected for changes in survey effectiveness (Shuter et al. 1987; Shuter and Ridgway 2002). Data also came from a multi-year spawning study conducted on Opeongo Lake from the 1980s to the present, as well as from detailed studies of growth and maturation conducted in 1981-1982 and 2000-2003 on Provoking and Opeongo Lakes (Ridgway et al. 1991; Dunlop et al. 2005a, b). The empirical relationships used to parameterize the model are depicted in Figure 1 and detailed parameter values are provided in Appendix 1.

Probabilistic maturation reaction norms

To account for the inherent stochasticity in the maturation process (Bernardo 1993), Heino et al. (2002) introduced the probabilistic maturation reaction norm (PMRN), defined as the probability of an individual to mature during the next season as a function of its current size and age. The midpoint of such a PMRN is defined as the size, separately for each age, at which the

probability of maturing is 50% (Figure 1). The probabilistic envelope around the midpoint is given by the contour lines of equal maturation probability, ranging from just over 0 to just under 100% probability of maturation (Figure 1). The envelope's width is defined as the size interval, separately for each age, within which the probability of maturation rises from, say, 1% to 99%. This PMRN approach has been used in recent studies to isolate the influence of growth on maturation (Dunlop et al. 2005b) and to reveal shifts in PMRNs suggestive of evolutionary responses to selective harvest (Grift et al. 2003; Barot et al. 2004b; Olsen et al. 2004, 2005). In our model, we consider a linear PMRN, with an evolving midpoint slope and intercept, and a constant width among ages. We model linear reaction norms (de Jong 1990) to reduce model complexity and we consider the slope and intercept of the reaction norm as separate evolving traits because they experience different selective pressures (e.g., Brommer et al. 2005).

Genetic structure

We use quantitative genetics principles (Falconer and Mackay 1996) to model the underlying genetic component of our populations. We assume that phenotypic plasticity (in maturation) is heritable by modeling genetically-based reaction norms that are passed from parents to offspring (e.g., Brommer et al. 2005; Nussey et al. 2005). The evolving traits that describe the reaction norms (PMRN intercept and slope) are initially assumed to be normally distributed with given mean and variance. Both traits are passed on to offspring with incomplete inheritance.

Each individual in the population has a PMRN that is characterized by a midpoint slope (X), midpoint intercept (Y), and envelope width. The distribution of individual PMRNs in the population represents the genetic variance (Noordwijk 1989; Windig 1994). The population-level PMRN is the mean of the individual PMRNs, and its envelope width represents the phenotypic variation in length at maturation for each age. At each age a, the population's phenotypic

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

variance in length at maturation, $\sigma_{P,a}^2 = \sigma_{G,a}^2 + \sigma_{E,a}^2$, is composed of its genetic variance in length

at maturation, $\sigma_{G,a}^2$, and its variance in length at maturation resulting from environmental factors,

$\sigma_{E,a}^2$ (Noordwijk 1989; Falconer and Mackay 1996). Heritability h_a^2 in length at maturation at

age a is given by the ratio between $\sigma_{G,a}^2$ and $\sigma_{P,a}^2$ (Falconer and Mackay 1996). At each age a,

the population's genetic variance in length at maturation is

$$\sigma_{G,a}^2 = a\sigma_X^2 + \sigma_Y^2 \; , \tag{1}$$

where σ_X^2 and σ_Y^2 are the population's additive genetic variance in midpoint slope and intercept,

respectively, at age a. Equation (1) follows directly from the assumed linearity of PMRNs.

In our model, we assume levels of genetic variance for the two traits X and Y and, together

with an empirical estimate of phenotypic variance in length at maturation, use it to estimate

heritability in the initial population (see Section on "Initial population structure" below). The

genetic variances are then free to change through time.

Initial population structure

The parameters of the initial population were estimated from Opeongo Lake creel data

collected on the earliest studied cohorts (1930s and 1940s). In our model, the introduced

population consists of 200 yearlings (individuals of age 1) with a normal distribution of initial

body sizes based on the mean and standard deviation of the Opeongo 1932 year class. Back-

calculations (Francis 1990) of body lengths at age 1, measured from scale samples collected from

individuals of the 1932 cohort, were used to estimate the mean and standard deviation for

yearling body size (using the validated back-calculation technique described in Dunlop and

Shuter 2006).

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

The initial population-level PMRN midpoint slope, midpoint intercept, and envelope width were estimated empirically from Opeongo Lake creel data using the procedure introduced by Barot et al. (2004a). This procedure involves deriving the probability of maturing at a given age a and size s,

$$p_m(a,s) = \frac{o(a,s) - o(a-1, s - \Delta s(a))}{1 - o(a-1, s - \Delta s(a))}, \tag{2}$$

from the maturity ogive $o(a,s)$ describing the probability of being mature at a given age and size (calculated using logistic regression) and from the growth increment Δs from age a-1 to age a (Barot et al. 2004a). We pooled the 1930s-40s cohorts to obtain a representative sample. Sufficient data allowed the estimation of the population-level PMRN for ages 4, 5, and 6; a linear regression of the midpoints of these three ages was then used to estimate the midpoint slope and intercept of the initial population's PMRN (Figure 1a). The 1% and 99% maturation probability percentiles of 4-year-olds (the age class with the largest sample size) were used to determine the width of the initial population's PMRN (Figure 1a).

Given that the actual distribution of variation between midpoint slope and intercept is unknown for the considered smallmouth bass populations, we parsimoniously assume the same 10% level for the coefficients of variation (CV = 100*standard deviation/mean) in both traits in the initial population; we chose 10% because it produces a realistic value of heritability (see below). All individuals in the initial population are then assigned a PMRN midpoint slope and intercept from a normal distribution with a mean equal to the population-level PMRN's midpoint (Figure 1a) and a standard deviation given by the assumed coefficient of variation (10%) in midpoint slope and intercept. To examine robustness, we also determined the sensitivity of our model's results to 99 other combinations of the two coefficients of variation (Appendix 2).

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

We calculated the heritability ($\sigma_{G,a}^2 / \sigma_{P,a}^2$) for 4-year-olds in our initial population. We chose this age group because this is the most common age at maturation and sample sizes are accordingly large. The value of genetic variance ($\sigma_{G,a}^2$) was calculated from Equation (1) and our assumed coefficients of variation. The initial population-level PMRN width for age 4 represents the range of body sizes, for this age, over which maturation occurs and was therefore used as our estimate of phenotypic variance ($\sigma_{P,a}^2$) in size at maturation for this age. Using this approach, we estimated the initial population's heritability in size at maturation for age 4 as ~0.26, which is in accordance with published estimates of heritabilities in life history traits (Mousseau and Roff 1987; Law 2000).

Maturation and reproduction

In any given year, immature individuals in our model become mature according to the maturation probability given by their PMRN in conjunction with their age and size. In our model, mating is size-assortative and occurs between pairs of mature individuals (assuming a 1:1 sex ratio) that are similar in body size. We parsimoniously assume strict size-assortative mating because there is evidence that smallmouth bass are strongly size-assortative in mate preference (Ridgway et al. 1991; Mackereth et al. 1999) and we did not want to increase model complexity by introducing an additional parameter describing strength of the preference (we note that relaxing this assumption does not change the direction of predictions but does cause a slight increase in the magnitude of evolutionary change in response to size-selective mortality).

The number of offspring produced by a reproductive pair is estimated from the body size L of the largest parent in the pair following an empirically derived allometric relationship (Figure 1b),

$$F_I = (H_1 L)^{H_2} , \tag{3}$$

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

with constants H_1 and H_2. The number of new individuals recruiting to the population at age 1 is determined from a modified Ricker-type stock-recruitment function (Figure 1c),

$$r = AS_a^{\ d} e^{-bS_a + cT} \ ,$$
(4)

where S_a is the number of adults, T is the mean air temperature for June through September (kept constant at 15 °C), and A, b, c, and d are empirically determined constants, based on a detailed analysis of annual variation in recruitment, adult population size, and summer air temperatures for the Opeongo Lake population over the period 1937-1992 (Shuter and Ridgway 2002). The survival probability from eggs to age 1 is defined as the ratio between r and the total number of eggs produced by the mature population. As stock-recruitment relationships can be highly variable, we tested our model's sensitivity to adding stochastic noise to the recruitment process (Appendix 2).

To model the inheritance of quantitative traits, we assume that offspring trait values are equally determined by maternal and paternal trait values. In particular, the PMRN midpoint slope and midpoint intercept of each newborn are drawn from a normal distribution centered on the corresponding mid-parental values (mean of the two parent's trait values) and possessing a variance σ_O^2 equal to half the population variance $\sigma_{M,F}^2$ in the parental generation (Cavalli-Sforza and Feldman 1976; Baskett et al. 2005),

$$\sigma_O^2 = \frac{1}{2}\sigma_{M,F}^2 \ .$$
(5)

This ensures that the inheritance process maintains the population variance and follows from the parsimonious assumption that the maternal σ_M^2 and paternal σ_F^2 trait variances are equal.

Somatic growth

We use the biphasic growth model proposed by Lester et al. (2004) to describe somatic growth. Accordingly, the growth of immature individuals is linear, with a mean growth rate $\overline{h}_i$ calculated from the population abundance D using a simple variant of the competition equation described by Begon et al. (1996),

$$\overline{h}_i = \frac{h_{\max}}{1 + jD^q} \; , \tag{6}$$

where j and q are constants and $h_{\max}$ is the maximum growth rate (at $D = 0$). Equation (6) provides a good description of the temporal association between growth and abundance exhibited by the Opeongo Lake population (Figure 1d). In the model of Lester et al. (2004), mature individuals grow according to von Bertalanffy's growth function, reaching length

$$L_a = L_\infty (1 - e^{-k(a - a_0)}) \tag{7}$$

at age a, with parameters

$$L_\infty = \frac{3h_i}{g} \; , \tag{8}$$

$$k = \ln(1 + \frac{g}{3}\Delta a) \; , \tag{9}$$

and

$$a_0 = a_m + k^{-1} \ln(1 - \frac{g}{3}a_m) \; , \tag{10}$$

where g is the reproductive investment rate, Δa is the increment between age classes (1 year), and a_m is the age at which the "decision" to mature is made (this equals the age at maturation in our

model). The reproductive investment rate g was estimated from the growth curve of mature

Opeongo Lake smallmouth bass (following Lester et al. 2004) captured in 2000-2001 (Dunlop et

al. 2005a) and, for simplicity, is assumed to be identical and constant over time for all

individuals. To allow variation in growth among individuals, growth rates h_i are randomly

drawn, separately in each year, from a normal distribution with mean $\overline{h_i}$ and standard deviation

h_s calculated from Opeongo Lake creel data (Shuter et al. 1987).

Mortality

Age-specific annual mortality probabilities were measured from Opeongo Lake creel data

(Shuter et al. 1987) and are applied annually to individuals of ages 1 to 3, $m_{1-3} = 0.27$, and of

ages 4 and older, $m_{4+} = 0.54$. On top of this background mortality, we apply different levels of

selective harvest mortality from the time of introduction onwards. We apply selective annual

mortality probabilities of 0 to 0.5 (in increments of 0.1) at the individual level on either (i) age-0

individuals or (ii) individuals above a minimum size limit. We chose 18 cm as the minimum size

limit because this is the hypothesized size at which mortality differences begin to emerge

between the Provoking Lake and Opeongo Lake populations (Dunlop et al. 2005a). The size-

selective mortality is applied to individuals regardless of maturation status; typically, the 18 cm

size class contains both juveniles and adults (Dunlop et al. 2005a). We also tested the sensitivity

of our model results to decreasing m_{4+} to 0.27 and to increasing the minimum size limit to

between 20 and 28 cm (Appendix 2).

Parental care

We explore the consequences of parental care by considering three different ecological

mechanisms. To delineate the evolutionary consequences of parental care, we investigate how

the evolutionary response to a 0.3 probability of size-selective mortality, applied to individuals

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

above an 18 cm size limit, varies in the presence and absence of each of the three mechanisms. We also assess the evolutionary effect of all three mechanisms combined.

For the first mechanism, we assume that small males possess insufficient energy reserves for nest guarding when population density is high. Accordingly, we introduce a dependence of the number R of breeding mature individuals on the abundance D_m of mature individuals in the population,

$$R = C_1 D_m{}^{C_2} \tag{11}$$

where C_1 and C_2 are empirically based constants (Figure 1e). The largest R mature individuals in the population are then chosen for breeding, implying that for $R < D_m$ the smallest mature individuals in the population do not breed.

For the second mechanism, we assume elevated mortality levels for parents that breed at small body sizes. We used mark-recapture data on nesting males in Opeongo Lake to derive the relationship between the size of a parent and its mortality (Figure 1f; Appendix 3). We incorporate this second mechanism by applying the mortality probability $M_{p,L}$ to the largest parent in each reproducing pair, following reproduction.

For the third mechanism, we assume reduced survival of offspring of small-sized parents. Due to a lack of empirical data for calibrating this effect, we assume a linearly decreasing relationship between the mortality probability of the offspring produced by a given pair of parents in a given year and the size L of the pair's larger parent. Specifically, we assume this mortality probability to decrease from a maximum of $\widetilde{M}_{p,0} = 0.5$ at $L = 0$ cm to a minimum of 0 at $L \geq L_0$,

$$\widetilde{M}_{p,s} = \widetilde{M}_{p,0}(1 - L/L_0)_+ \ . \tag{12}$$

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

We chose $L_0 = 40$ cm because parents above this size appear to be particularly aggressive and effective nest guarders (E. Dunlop, unpublished data). We also varied $\widetilde{M}_{p,0}$ to observe the effect on model results (Appendix 2).

Results

Age-0 smallmouth bass mortality causes slower population expansion, lower population biomass and abundance, faster somatic growth rates, and maturation at slightly larger sizes (Table 1; Figure 2); however, there is little to no effect on the PMRN's slope and intercept (Figure 2e). Selective mortality of individuals above 18 cm in the absence of parental care has a small influence on population abundance and somatic growth rate, but causes a substantial decrease in population biomass and in age and size at maturation (Table 1; Figure 2); these changes are accompanied by large decreases in the PMRN's slope and intercept (Figure 2f).

Including effects of parental care generally reduces the rate of evolution. The 100-year response in the PMRN to a 0.3 probability of size-selective mortality is not appreciably different when we make the number of small-sized parents that actually breed dependent on the abundance of adults (mechanism 1), but it is significantly reduced when we include a survival cost for small parents (mechanism 2), include a survival cost for the offspring of small-sized parents (mechanism 3), or combine all three mechanisms (Table 1; Figure 3). In addition, final population sizes are significantly reduced when these parental care effects are included (Table 1).

Discussion

Our model predicts that, at least in the absence of parental care, introduction of a population into a system with high size-selective mortality causes a dramatic shift of the PMRN,

16

corresponding to evolution towards smaller sizes and younger ages at maturation. This is because individuals able to reach maturation prior to succumbing to mortality are more likely to reproduce and pass on their traits to the next generation. These predictions are supported by observations of PMRN shifts in several stocks of cod *Gadus morhua* (Barot et al. 2004b; Olsen et al. 2004, 2005) and plaice *Pleuronectes platessa* (Grift et al. 2003) that have been subject to the type of selective mortality we considered in our model. In northern cod, the midpoint of the PMRN dropped by 10 cm in only 7 years (Olsen et al. 2004), providing empirical evidence that the magnitude of responses predicted from our model are also possible in nature. However, these predictions contrast sharply with the observed stability of the PMRN exhibited by both the Provoking and Opeongo Lake smallmouth bass populations after 100 years of living under different mortality rates (Dunlop et al. 2005a, b).

Not surprisingly, age-0 smallmouth bass mortality causes no evolutionary response in the PMRN. In our model, age-0 smallmouth bass mortality is applied to individuals during their first year of life and is not applied throughout the juvenile period. We take this approach because many predators of smallmouth bass are relatively small in body size and tend to feed on the smallmouth bass' egg and larval stages (Knotek and Orth 1998; Dorn and Mittelbach 2004; Steinhart et al. 2004). Our approach is in contrast to models in which the life history strategy affects survival throughout the juvenile period (e.g., Abrams and Rowe 1996) or in which the considered juvenile mortality extends right up to maturation (e.g., Ernande et al. 2004); in these models, juvenile mortality is predicted to cause evolution in the age or size at maturation. However, because mortality during the age-0 phase occurs far in advance of maturation, so that individuals have to undergo such mortality regardless of their maturation traits, it is clear that the age-0 smallmouth bass mortality in our model exerts no selective pressure on the PMRN.

The detailed studies that have been conducted on the Provoking Lake and Opeongo Lake smallmouth bass populations permit comparisons between model predictions and empirical observations. Our model predicts that introduction to a system with low mortality on age-0 individuals produces higher population density, slower somatic growth rates, and smaller sizes at maturation. These model predictions match the empirical observations of the Provoking Lake population, where evidence suggests that there is less predation of age-0 individuals relative to the Opeongo Lake population (Dunlop et al. 2005a). Empirical evidence also suggests that mortality on typically adult size classes is higher in Provoking Lake than in Opeongo Lake (Orendorff 1983; Dunlop et al. 2005a); for example, mortality probabilities following nest guarding, estimated from return rates of tagged individuals, are related to body size (Figure 1f) and average 89% in Provoking Lake and 63% in Opeongo Lake (Dunlop et al. 2005a). These differences in mortality are not due to recreational fishing because harvest is low in the Opeongo Lake population (Shuter et al. 1987) and very low (less than 3% per year) in the Provoking Lake population (Orendorff 1983), but are instead likely related to the low availability of large prey in Provoking Lake (Dunlop et al. 2005a). Interestingly however, these differences in size-selective mortality between the Provoking Lake and Opeongo Lake populations have not led to detectable evolutionary divergence in their PMRNs (Dunlop et al. 2005b).

The predictions of our model, namely that parental care reduces the rate of evolutionary response to mortality, are supported by the above observations on the Opeongo Lake and Provoking Lake populations showing no evolutionary divergence in their PMRNs despite between-population differences in size-selective mortality. Inclusion of parental care mechanisms in our model alters the selective environment and reduces the evolutionary response in the PMRN. In the wild, larger parents not only possess higher energy reserves to better survive the energetic costs of nest guarding (Mackereth et al. 1999), but are also better able to

defend their brood from predators (Wiegmann and Baylis 1995; Knotek and Orth 1998). Large body size also has its benefits in species without parental care, in which larger, more experienced spawners produce eggs and larvae with higher survival probabilities (e.g., Trippel 1998). Our model illustrates that the selective pressures favoring large body size in parents might counteract the selective pressures towards maturation at smaller body size imposed by mortality on larger individuals, thereby altering the total selective forces acting on the PMRN. However, this is not to say that very intensive harvest will not cause substantial evolution of the PMRN in a species with parental care; rather, the evolutionary response to intense harvest would likely be lessened in a species with parental care compared to one without parental care because of the opposing selective forces. This increase in 'evolutionary inertia', imposed on the PMRN by parental care effects, has demographic consequences: final population sizes in the presence of parental care are reduced. This reduction occurs because parental care effects constrain the compensating increases in population growth rate that arise from evolutionary adaptation in the PMRN. This finding suggests that the presence of parental care can impose additional limitations on the ability of a population to persist, by adaptation, in the face of the added mortality imposed by intense harvest.

Observed patterns in the age and size at maturation of smallmouth bass support our hypothesis that the survival costs associated with parental care are significant factors in this system. The lower range of ages and sizes at maturation that our model predicts for a species without parental care experiencing the high-mortality regimes are not commonly observed in smallmouth bass, neither in the Provoking Lake or Opeongo Lake populations (Dunlop et al. 2005a), nor in wild populations of smallmouth bass in general (Dunlop 2005). However, once we include parental care in the model, maturation occurs across a range of more typical ages and

sizes, suggesting that accounting for this life history characteristic improves the realism of our model.

Our evolutionary model includes several simplifications. First, the model describes evolution in quantitative traits rather than genes. Second, we parsimoniously assume coefficients of genetic variation of 10% in our initial population. As expected (Falconer and Mackay 1996), the speed of evolution is positively related to the assumed values (Appendix 2). Encouragingly, however, our assumed coefficient results in an estimated heritability of length at maturation for 4-year-olds (~0.26) that is the same as the mean value of 0.26 reported for life history traits by Mousseau and Roff (1987). Third, we assume no genetic correlation between the two evolving quantitative traits, and we do not consider potential joint evolution in many other interesting life history traits, such as reproductive investment or somatic growth rate. We did not allow these other traits to evolve in the model because the inclusion of PMRNs already is a substantial advancement over previous models and we wanted to keep model analyses and predictions reasonably simple. However, there is evidence that reproductive investment increases with higher mortality (Reznick et al. 1990; Lester et al. 2004) and that rapid evolution of somatic growth rate can occur in response to selective mortality on large individuals (Conover and Munch 2002); it is thus conceivable that size-selective mortality could induce evolutionary shifts in these other life history traits in the smallmouth bass.

A promising extension of our model would be to include sex differences. In our model, males and females are assumed to be identical, with a 1:1 sex ratio. We made this simplification because there is no sexual dimorphism in the somatic growth rates of smallmouth bass (Dunlop et al. 2005a). This is likely because females invest a large amount of energy into gonads, whereas males invest energy into parental care, leading to a similar reduction in somatic growth in both sexes. If we had modeled males and females separately and allowed only males to exhibit

parental care, the impact on the parental care results would have likely been minimal because of size-assortative mating (Ridgway et al. 1991; Mackereth et al. 1999). In the wild, small females might not be able to breed if there are no small males for them to breed with (Dunlop et al. 2005a); if the number of small males that breed is dependent on population density (our first parental care mechanism), the same relationship will hold true for small females. Similarly, because of size-assortative mating, the offspring of large females will also have a higher probability of survival (our third parental care mechanism). When considering a mortality cost for small parents (our second parental care mechanism), we only apply this cost to one of the parents to mimic a situation where only one parent is providing care. Therefore, modeling separate sexes was not necessary for the purposes of this study but, in future, could provide further insights depending on the focal species and research question at hand.

The eco-genetic modeling framework presented here provides a powerful tool for studying the mortality-induced evolution of PMRNs. The majority of related models to date have not adequately considered phenotypic plasticity in the maturation process, since they directly modeled age and/or size at maturation as quantitative traits, without accounting for their dependence on the environment (e.g., Law 1979; Abrams and Rowe 1996; Heino 1998; Martinez-Garmendia 1998; Ratner and Lande 2001). The model by Ernande et al. (2004) did account for phenotypic plasticity by following the evolution of MRNs, but employed deterministic maturation dynamics and focused on the prediction of evolutionary endpoints rather than of the time course of evolutionary change. In Ernande et al. (2004), size-selective harvest of individuals larger than a minimum size limit caused evolutionary shifts of the MRN towards younger ages and smaller sizes. While these findings are qualitatively similar to ours, using an eco-genetic modeling approach readily allowed for several novel developments. First, we could model maturation as being probabilistic, which is likely more realistic given the considerable

stochasticity involved in the maturation process (Heino et al. 2002). This added realism actually alters the model's predictions by slowing down the evolutionary response as compared with models in which MRNs are unrealistically treated as deterministic (Appendix 2). Second, our choice of model allowed examination of the speed of evolution, something that is not possible based on traditional optimization models (e.g., Law 1979) or adaptive dynamics models (e.g., Heino 1998; Ernande et al. 2004), both of which focus on evolutionary endpoints instead. Third, our model permitted somatic growth rates to vary with population density, a realistic feature missing from most related previous evolutionary models (e.g., Martinez-Garmendia 1998; Ratner and Lande 2001; Ernande et al. 2004; Tenhumberg et al. 2004; Baskett et al. 2005). Modeling somatic growth as density-dependent is important in the context of mortality-induced evolution: while mortality can influence growth through its impact on population abundance, growth controls an individual's body size, which in turn influences its fitness, especially in an environment where mortality is size-selective. Accounting for density-dependent growth is also important when examining the dynamics of recently introduced populations, as the density and growth of such populations undergo considerable temporal shifts in the wake of the introduction. Our analysis of the effect of growth on the evolutionary process clearly illustrates the danger in assuming a constant growth rate that does not change with population abundance: the rates of evolution can be either severely over- or under-estimated when density-dependence is not included (Appendix 2). Also, we would not have been able to predict the plastic effect of age-0 mortality (which alters abundance) on growth and maturation patterns without the presence of density-dependent growth.

Finally, and perhaps most importantly, our results are novel because we show that inherent selective forces, such as those produced by parental care, can greatly alter the evolutionary response typically observed under size-selective harvest. This underscores the

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

importance of adequately reflecting the life history characteristics of the considered species when assessing its vulnerability to the selective pressures imposed by exploitation.

Appendix 2. Sensitivity analyses

We performed sensitivity analyses on various model parameters and assumptions. We carried out our sensitivity analyses with size-selective mortality applied to individuals larger than 18 cm and examined the effect of the varied parameters or assumptions on the final position (i.e., in year 100) of the probabilistic maturation reaction norm (PMRN) midpoint. The measure of sensitivity used is therefore the amount of evolution observed in the PMRN over a 100-year period.

(i) *Maximum mortality probability in the third parental care mechanism*

We varied the $\widetilde{M}_{p,0}$ in Equation (12) between 0.1 and 0.5 to explore the consequences of the third parental care mechanism. We found that as we increase the mortality rate $\widetilde{M}_{p,0}$ applied to the offspring of small parents, the evolutionary response to size-selective mortality decreases (Table A2.1).

(ii) *Minimum size limit in the size-selective mortality regime*

We tested the effect of raising the minimum size limit in our size-selective harvesting regime to 20, 22, 24, 26, and 28 cm. The results of this sensitivity analysis show that raising the minimum size limit between 20 and 22 cm causes a slight increase in the amount of PMRN evolution, whereas raising the minimum size limit beyond 24 cm lessens the amount of evolution observed (Table A2.1).

(iii) *Combination of age-0 mortality and size-selective mortality*

We determined the combined effect of age-0 mortality of 0.3 and size-selective mortality (on individuals greater than 18 cm) of 0.3; this causes only a minor decrease in the amount of PMRN evolution compared to a scenario with only 0.3 mortality probability on individuals greater than 18 cm (Table A2.1).

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

(iv) *Stochasticity in the stock-recruitment relationship*

We added normally distributed noise into the stock-recruitment relationship by drawing recruitment numbers randomly from a normal distribution centered on the deterministic number of recruits (from Equation 4) with a standard deviation equal to either 10% or 20% of the number of recruits. This noise has little influence on the evolutionary response with a slight tendency to increase the amount of PMRN evolution (Table A2.1).

(v) *Deterministic maturation reaction norm*

To test the implications of removing stochasticity from the maturation process, we modeled the response of a deterministic maturation reaction norm to size-selective mortality. Not surprisingly, making the maturation reaction norm deterministic results in a larger evolutionary response (Table A2.1).

(vi) *Density-dependent growth*

In our test of the sensitivity of model results to density-dependence, we disregarded the relationship between growth rate and population abundance. Immature growth then differed between individuals and years only stochastically around the mean immature growth rate $\overline{h}_i$ of the initial population. The results show that, in the absence of density dependence, the amount of PMRN evolution decreases when the mean immature growth rate is increased (Table A2.1). When the mean immature growth rate is held constant at a slow rate (i.e., at 6 cm year^{-1}), the amount of PMRN evolution observed is larger compared to results with density-dependence; the opposite pattern is observed when the mean immature growth rate is held constant at higher rates (i.e., at and beyond 7 cm year^{-1}; Table A2.1).

(vii) *Background mortality*

We performed a sensitivity analysis on the background level of age-specific mortality applied to older individuals (ages 4+). We did this to ascertain whether the amount of evolution observed in response to size-selective mortality is larger than the effect of the elevated age-specific mortality of older individuals. To do so, we altered the background age-specific annual mortality of older individuals from 0.54 (the original level) to 0.27 in order to make it equal to that of younger individuals, while at the same time applying a size-selective annual mortality of 0.5 to individuals above 18 cm. The results indicate that decreasing the background mortality of older individuals reduces the amount of evolution in response to size-selective harvest: the PMRN midpoint for a 5-year-old decreases by 10.82 cm with the original background mortality of 0.54 and by 8.36 cm when the background mortality is reduced to 0.27. Therefore, the evolutionary response with the reduced background mortality is still substantial and is significantly larger than the difference in response between the two background mortalities.

(viii) *Coefficients of genetic variation in the initial population*

We performed a sensitivity analysis on the initial population's coefficients of genetic variation in the PMRN midpoint slope and intercept. We tested 100 combinations, with both coefficients of variation ranging between 1% and 10% in steps of 1%, and observed the effect on model results. We performed this sensitivity analysis using an annual size-selective mortality of 0.5 applied to individuals above 18 cm. As expected, we found that the amount of evolution in the PMRN slope increases with the initial variance of this slope, and the amount of evolution in the PMRN intercept increases with the initial variance of this intercept (Figure A2.1).

Table A2.1. Sensitivity of changing model parameters and assumptions on the final position of the probabilistic maturation reaction norm (PMRN) midpoint slope and intercept after 100 years of annual selective mortality probability.

Modification made in sensitivity analysis	Targets of selective mortality	Selective mortality probability	PMRN slope (cm year^{-1})	PMRN intercept (cm)
Baseline scenario[a]	>18 cm	0.3	1.86	12.08
$\widetilde{M}_{p,0} = 0.1$	>18 cm	0.3	1.87	12.30
$\widetilde{M}_{p,0} = 0.2$	>18 cm	0.3	1.87	12.32
$\widetilde{M}_{p,0} = 0.3$	>18 cm	0.3	1.87	12.86
$\widetilde{M}_{p,0} = 0.4$	>18 cm	0.3	1.88	13.30
$\widetilde{M}_{p,0} = 0.5$	>18 cm	0.3	1.88	13.60
Minimum size limit	>20 cm	0.3	1.85	12.13
Minimum size limit	>22 cm	0.3	1.84	11.86
Minimum size limit	>24 cm	0.3	1.82	12.13
Minimum size limit	>26 cm	0.3	1.84	12.72
Minimum size limit	>28 cm	0.3	1.84	13.37
Age-0 and size-selective	age-0 & >18cm	0.3 + 0.3	1.88	13.05
10% stochasticity in SR[b]	>18 cm	0.3	1.84	12.00
20% stochasticity in SR[b]	>18 cm	0.3	1.86	11.86
Deterministic MRN[c]	>18 cm	0.3	1.85	10.05
Constant mean growth[d] = 6 cm year^{-1}	>18 cm	0.3	1.84	11.58

Erin S. Dunlop, Brian J. Shuter, Ulf Dieckmann

Constant mean growth[d] = 7 cm year^{-1}	>18 cm	0.3	1.87	14.17
Constant mean growth[d] = 8 cm year^{-1}	>18 cm	0.3	1.94	16.73
Constant mean growth[d] = 9.12[e] cm year^{-1}	>18 cm	0.3	1.98	18.10
Constant mean growth[d] = 10 cm year^{-1}	>18 cm	0.3	1.99	18.69

[a]The baseline scenario is included for comparison; it is given by the standard results (i.e., without any of the modifications considered in the sensitivity analyses) for 100 years of selective mortality probability of 0.3 on individuals above 18 cm.

[b]SR = stock-recruitment relationship (Equation 4).

[c]The slope and intercept represent a deterministic maturation reaction norm with vanishing envelope width.
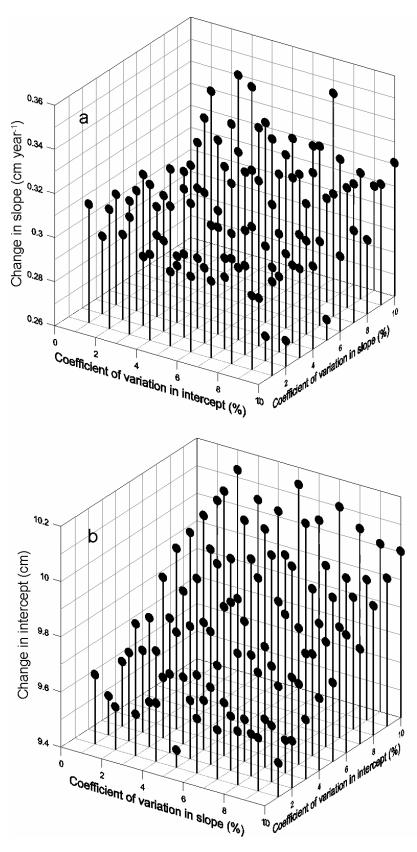

[d]Density-dependent growth disregarded here

[e]Note that $\overline{h_i} = h_{max} = 9.12$ cm follows from Equation (6) for $D = 0$

Appendix 3. Estimation of size-dependent parental mortality

From 1997 to 2003, all of the nesting males in Jones Bay (perimeter = 5 km) of Opeongo

Lake were captured with fishing rods, had their body sizes measured, had 3-6 scales removed for

aging purposes, were tagged with internal passive integrated transponder tags (Biomark, Boise

Idaho) and external t-bar tags (Halprint, Australia), and were released back onto their nests within

5 minutes (Ridgway et al. 1991). Smallmouth bass show extremely high nest-site fidelity, as

males that nest in multiple years tend to return to within close proximity of their original nest site;

in the Opeongo Lake population, 94% of previously nesting males return to within 200 m and

35% return to within 20 m (the modal distance category) of their original nest site (Ridgway et al.

2002). Therefore, by sampling all nesting males in Jones Bay in multiple years, it was possible to

identify which male parents did not return to nest in a subsequent year. Under the reasonable

assumptions that the number of males straying outside of the sampling area was negligible and

that those that did not return had suffered mortality, the size-dependent annual mortality

probability was estimated by dividing, separately for each size class, the number of males that did

not return to nest in a subsequent year by the total number of males that were tagged (following

an approach similar to that developed in Dunlop et al. 2005b). These annual mortality

probabilities of reproducing individuals $M_{r,L}$ were converted to instantaneous mortality rates

$I_{r,L}$, and regressed on body size L, $I_{r,L} = I_s L + I_i$ (Figure 1f shows this relationship in terms of

annual mortality probabilities). We then assumed that the background annual mortality

probability of 0.54 experienced by older fish was the annual mortality probability M_b of non-

reproducing individuals. The increase in annual mortality probability induced by reproduction

for a parent of body size L is thus given by

$$M_{p,L} = M_b - M_{r,L} \ . \tag{A3.1}$$
