## Abstract

Dispersal modulates gene flow throughout a population's spatial range. Gene flow affects adaptation at local spatial scales, and consequently impacts the evolution of reproductive isolation. A recent theoretical investigation has demonstrated that local adaptation along an environmental gradient, facilitated by the evolution of limited dispersal, can lead to parapatric speciation even in the absence of assortative mating. This and other studies assumed unconditional dispersal, so individuals start dispersing without regard to local environmental conditions. However, many species disperse conditionally; their propensity to disperse is contingent upon environmental cues, such as the degree of local crowding or the availability of suitable mates. Here, we use an individual-based model in continuous space to investigate by numerical simulation the relationship between the evolution of threshold-based conditional dispersal and parapatric speciation driven by frequency-dependent

*Email addresses:* [joshua.payne@dartmouth.edu](mailto:joshua.payne@dartmouth.edu) (Joshua L. Payne), [mazzucco@iiasa.ac.at](mailto:mazzucco@iiasa.ac.at) (Rupert Mazzucco), [dieckmann@iiasa.ac.at](mailto:dieckmann@iiasa.ac.at) (Ulf Dieckmann)

competition along environmental gradients. We find that, as with unconditional dispersal, parapatric speciation occurs under a broad range of conditions when reproduction is asexual, and under a more restricted range of conditions when reproduction is sexual. In both the asexual and sexual cases, the evolution of conditional dispersal is strongly influenced by the slope of the environmental gradient: shallow environmental gradients result in low dispersal thresholds and high dispersal distances, while steep environmental gradients result in high dispersal thresholds and low dispersal distances. The latter, however, remain higher than under unconditional dispersal, thus undermining isolation by distance, and hindering speciation in sexual populations. Consequently, the speciation of sexual populations under conditional dispersal is triggered by a steeper gradient than under unconditional dispersal. Enhancing the disruptiveness of frequency-dependent selection, more box-shaped competition kernels dramatically lower the speciation-enabling slope of the environmental gradient.

*Keywords:* Frequency-dependent selection; sexual reproduction; speciation; evolutionary branching; competition kernels

## 1 **1. Introduction**

2 Dispersal is a topic of central importance in ecology and evolutionary  
3 biology (Ronce, 2007), influencing spatial distributions of genetic diversity  
4 (Wright, 1969), adaptation to local environments (Gandon et al., 1996; Lenor-  
5 mand, 2002), and spatial population dynamics (Kendall et al., 2000). Disper-  
6 sal mediates gene flow throughout a population’s spatial range and, through  
7 isolation by distance (Wright, 1943), thus affects the evolution of reproduc-

8 tive isolation (Barton, 2001; Eppstein et al., 2009).

9 Quantitative model-based studies have demonstrated that environmental  
10 gradients promote parapatric speciation driven by frequency-dependent com-  
11 petition: with limited dispersal, local adaptation and competition along the  
12 gradient cause disruptive selection (Doebeli and Dieckmann, 2003; Leimar  
13 et al., 2008). In contrast, long-range dispersal increases gene flow throughout  
14 the population, reduces local adaptation and frequency-dependent competi-  
15 tion, and thus limits the possibility of parapatric speciation (Doebeli and  
16 Dieckmann, 2003).

17 In a recent study, Heinz et al. (2009) extended the model of Doebeli and  
18 Dieckmann (2003) by allowing for the evolution of dispersal distance. A key  
19 finding of their work (Heinz et al., 2009) is that short-range dispersal evolves  
20 in conjunction with parapatric speciation events. This leads to isolation by  
21 distance, providing an alternative mechanism to assortative mate preference  
22 for the evolution of reproductive isolation in parapatry (Wright, 1943).

23 Heinz et al. (2009) considered unconditional dispersal. Accordingly, in-  
24 dividuals could not base their decision to disperse on salient environmental  
25 information, such as high local competition or low carrying capacity. Empiri-  
26 cal evidence, however, suggests that in many species, an individual's propen-  
27 sity to commence dispersing depends on the external environment (Ims and  
28 Hjermann, 2001), resulting in conditional dispersal. For example, pea aphids  
29 *Acyrtosiphon pisum* produce an increased proportion of winged dispersal  
30 morphs in the presence of an aphid alarm pheromone (Kunert et al., 2005);  
31 emigration rates in the collared flycatcher *Ficedula albicollis* increase when  
32 either the number or the condition of local offspring decrease (Doligez et al.,

33 2002), and dispersive mutants of the nematode *Caenorhabditis elegans* in-  
34 crease in prevalence in response to the random destruction of patches in  
35 experimental metapopulations (Friedenberg, 2003).

36 The present study investigates the relationship between parapatric spe-  
37 ciation and the evolution of conditional dispersal. We build upon a growing  
38 literature of theoretical models of conditional dispersal, which have consid-  
39 ered a variety of dispersal functions and environmental cues. For example,  
40 Travis and Dytham (1999) considered a conditional dispersal strategy that  
41 was linearly dependent on patch density and allowed its slope and intercept  
42 to evolve. Bach et al. (2007) considered a sigmoidal density-dependent dis-  
43 persal strategy and allowed its steepness and half-saturation point to evolve.  
44 Kun and Scheuring (2006), and later Travis et al. (2009), employed a gen-  
45 eral three-parameter density-dependent dispersal strategy able to capture  
46 numerous qualitatively different shapes. Metz and Gyllenberg (2001), and  
47 later Gyllenberg et al. (2008), utilized function-valued trait representations  
48 of conditional dispersal, which allowed for arbitrary functional forms. A  
49 common outcome of these models is the evolution of threshold-based disper-  
50 sal, where dispersal propensity is low below some critical environmental cue  
51 and then high above it. These theoretical results are consistent with em-  
52 pirical evidence that dispersal strategies are threshold-based in some species  
53 (Hodgson, 2002).

54 Dispersal is inherently risky. This is because any dispersal event either  
55 improves or worsens the environmental quality experienced by the disperser,  
56 without that individual having any chance to predict the outcome in advance  
57 of risking the dispersal event. Among the relevant factors influencing envi-

58 ronmental quality are local competition and scarcity of resources. Dispersal  
59 may allow an individual to escape from intrinsic resource scarcity, but comes  
60 at the potential expense of moving to a location where environmental quality,  
61 in those two regards, is even worse. An additional risk of dispersal comes  
62 from the chance of moving to an environment where the individual is less  
63 well adapted. Moreover, the movement event itself imposes mortality risks,  
64 such as increased exposure to predation (Ims and Andreassen, 2000). The  
65 evolution of threshold-based dispersal strategies highlights the fundamental  
66 tension between these potential costs and benefits of dispersive behavior.  
67 The evolved dispersal threshold reflects the point at which the benefits begin  
68 to outweigh the costs (Parvinen et al., 2003).

69 Here, we use an individual-based model in continuous space to investigate  
70 by numerical simulation the evolution of threshold-based dispersal strategies  
71 in spatially extended populations subject to frequency-dependent competi-  
72 tion along an environmental gradient. Systematically varying the environ-  
73 mental gradient and the phenotypic specificity of competition, we study the  
74 evolution of dispersal distances and thresholds, clarifying their impact on  
75 parapatric speciation. We investigate both asexual and sexual populations  
76 and competition kernels of different shapes, outline the parameter regions in  
77 which parapatric speciation occurs, and contrast these results with those ob-  
78 tained in the case of unconditional dispersal (Doebeli and Dieckmann, 2003;  
79 Heinz et al., 2009).

## 80 **2. Methods**

### 81 *2.1. Model Overview*

82 We consider a spatially explicit, individual-based, stochastic model in  
83 continuous space and time, which extends the model of Heinz et al. (2009)  
84 to the case of conditional dispersal.

85 The environment is assumed to be two-dimensional and continuous. One  
86 direction is ecologically neutral, while an environmental gradient exists in  
87 the other: The ecological character that confers the best adaptation to the  
88 local resource,  $u_0$ , varies linearly in space,

$$u_0(x) = a \left( x - \frac{1}{2} \right) + \frac{1}{2}, \quad (1)$$

89 where  $a$  is the slope of the environmental gradient (Roughgarden, 1972).

90 Individuals are described by their spatial location  $(x, y)$  in the unit square,  
91 an ecological character  $u$ , the threshold  $\tau$  and distance  $\delta$  defining their con-  
92 ditional dispersal, and – in the case of sexual populations – a mate search  
93 distance  $w$ . The ecological character  $u$  could describe a morphological, behav-  
94 ioral, or physiological trait, or a combination thereof. The bivariate character  
95  $(\tau, \delta)$  is used to parametrize the individual’s conditional dispersal function,  
96 which we assume takes the form of a step function (Eq. 8). The mate search  
97 distance  $w$  determines the probabilities of mate selection by spatial distance  
98 (Eq. 7). Apart from the preference for spatially proximal individuals, no  
99 form of assortativity or mating preference is considered.

100 The population is described by its current abundance  $N$  and the traits  
101 and locations of all individuals. A list of all model variables is given in Table

Population size	$0 \leq N$	300
Location	$0 \leq x_i, y_i \leq 1$	uniform in $[0, 1]$
Ecological trait	$0 \leq u_i \leq 1$	0.5
Dispersal threshold	$0 \leq \tau_i$	0.7
Dispersal distance	$0 \leq \delta_i \leq 1$	0.2
Mate search distance	$0 \leq w_i \leq 1$	0.2

Table 1: Model variables, their ranges, and initial values.

102 1. The configuration of the population changes over time due to birth and  
103 death events, which occur with (probabilistic) rates depending on the current  
104 population configuration.

### 105 *2.2. Mortality*

106 We assume a constant individual birth rate  $b_i = b$ , but the death rate  
107 depends on the individual's spatial location, phenotypic trait, and its com-  
108 petition for resources with all of the other individuals in the population. The  
109 intensity of both spatial and phenotypic competition increases as either spa-  
110 tial or phenotypic distance between any two individuals decreases. All these  
111 interactions are defined by kernels, which we now specify. Throughout, we  
112 use the following function (Roughgarden, 1974)

$$\Phi_{\sigma,n}(x) = \exp(-|x|^n/\kappa^n), \quad (2)$$

113 where

$$\kappa = \sqrt{\frac{\Gamma(1/n)}{\Gamma(3/n)}}\sigma \quad (3)$$

114 and  $\Gamma(x)$  is the gamma function. The kurtosis of  $\Phi$  can be adjusted by  
 115 varying  $n$ . For  $n = 2$ , the function is Gaussian. For  $n > 2$ , the function is  
 116 platykurtic, with a broader peak and thinner tails, relative to the Gaussian.  
 117 Independent of  $n$ ,  $\sigma$  measures the function's standard deviation.

118 The death rate  $d_i$  of an individual  $i$  is given by

$$d_i = \frac{n_{\text{eff}}(x_i, y_i, u_i)}{K(x_i, u_i)}, \quad (4)$$

119 where  $n_{\text{eff}}$  is the effective number of individuals with which individual  $i$  com-  
 120 petes

$$n_{\text{eff}}(x_i, y_i, u_i) = \frac{\Gamma(3/n)}{2\pi\sigma_s^2\Gamma(1+1/n)\Gamma(2/n)} \sum_{j=1, j \neq i}^N \Phi_{\sigma_s, n}(x_j - x_i) \cdot \Phi_{\sigma_s, n}(y_j - y_i) \cdot \Phi_{\sigma_c, n}(u_j - u_i), \quad (5)$$

121 and  $K(x_i, u_i)$  is the local carrying capacity, i.e., the density of individuals of  
 122 type  $u_i$  locally supported at location  $(x_i, y_i)$ ,

$$K(x_i, u_i) = K_0 \cdot \Phi_{\sigma_K, 2}(u_i - u_0(x_i)), \quad (6)$$

123 where  $K_0$  is the maximal carrying capacity and  $u_0(x_i)$  is the phenotype that  
 124 maximizes carrying capacity at spatial position  $x_i$  (Eq. 1). The prefactor in  
 125 Eq. 5 ensures that  $n_{\text{eff}} = K$  at demographic equilibrium in a monomorphic  
 126 population with gradient  $a = 0$ , and hence  $d_i \approx 1$ ; in the Gaussian case  
 127 ( $n = 2$ ), it reduces to  $1/(2\pi\sigma_s^2)$ . The parameters  $\sigma_s$  and  $\sigma_c$  specify how  
 128 quickly the strength of competition attenuates with spatial and phenotypic  
 129 distance, respectively. In Eq. 5, we consider both Gaussian ( $n = 2$ ) and  
 130 platykurtic ( $n = 3$ ) competition kernels, the latter of which being known

131 to facilitate adaptive divergence (Doebeli et al., 2006; Leimar et al., 2008).  
 132 However, in Eq. 6 we will use the Gaussian function  $\Phi_{\sigma,2}(x)$  with mean  $x$   
 133 and standard deviation  $\sigma$ . Carrying capacity (Eq. 6) thus decreases with  
 134 phenotypic distance from its maximum at  $u_0(x_i)$  according to a Gaussian  
 135 function with standard deviation  $\sigma_K$ .

136 We can define the fitness of an individual at every instant as the difference  
 137 between its current birth and death rate,  $f_i = b - d_i$ . The population-level  
 138 birth and death rates are given by  $B = bN$  and  $D = \sum_{i=1}^N d_i$ , respectively.  
 139 Thus, the population-level event rate is  $E = B + D$ .

### 140 2.3. Mating and Inheritance

141 For birth events, we consider both asexual and sexual reproduction. In  
 142 the asexual case, the phenotype  $(u, \tau, \delta)$  is inherited nearly faithfully from  
 143 parent to offspring, subject, at each birth event, to small mutations that dis-  
 144 place the offspring phenotype by a random increment drawn from a Gaussian  
 145 distribution with mean zero and standard deviation  $\sigma_m$ .

146 In the sexual case, when an individual  $i$  is chosen for reproduction it  
 147 selects a mate  $j \neq i$  based on spatial proximity, with probability

$$p_{ij} = \frac{\Phi_{w_i,2}(x_j - x_i) \cdot \Phi_{w_i,2}(y_j - y_i)}{\sum_{k=1, k \neq i}^N \Phi_{w_i,2}(x_k - x_i) \cdot \Phi_{w_i,2}(y_k - y_i)}. \quad (7)$$

148 Thus, mate choice is solely dependent upon spatial location, and does not  
 149 involve any form of assortment or sexual selection. However, the standard  
 150 deviation of the mate search area is  $w_i$ , which is an evolvable trait. The  
 151 parents  $i$  and  $j$  produce an offspring  $k$ , which inherits phenotypic trait val-  
 152 ues  $(u_k, \tau_k, \delta_k, w_k)$  from its parents by drawing from a Gaussian distribution

153 with mean equal to the mid-parental values  $\frac{1}{2}(u_i + u_j)$ ,  $\frac{1}{2}(\tau_i + \tau_j)$ ,  $\frac{1}{2}(\delta_i + \delta_j)$ ,  
154  $\frac{1}{2}(w_i + w_j)$  and with standard deviations equal to  $\frac{1}{2}|u_i - u_j|$ ,  $\frac{1}{2}|\tau_i - \tau_j|$ ,  $\frac{1}{2}|\delta_i - \delta_j|$ ,  
155  $\frac{1}{2}|w_i - w_j|$ . This captures the effects of segregation and recombination simul-  
156 taneously, and allows for a direct comparison with the results of Heinz et al.  
157 (2009), who introduced this specific offspring distribution with the argument  
158 that it preserves the variance of an existing Gaussian trait distribution in the  
159 well-mixed population. Experimentation with Gaussian distributions of con-  
160 stant width produced results that were statistically indistinguishable from  
161 those reported herein (paired t-test,  $p > 0.01$ ).

#### 162 2.4. Conditional Dispersal

163 In both the asexual and sexual case, the inherited dispersal characters  
164  $(\tau_k, \delta_k)$  affect how an offspring's spatial position is displaced relative to that  
165 of parent  $i$ . We thus consider natal dispersal, so individuals only move once  
166 in their lifetime and this movement occurs immediately after birth. The  
167 distance an offspring disperses is conditioned on local environmental quality,  
168 evaluated in terms of the individual's death rate  $d_k$ . This allows for the  
169 simultaneous assessment of both local competition and resource availability  
170 (Eq. 4). Conditional dispersal is assumed to take the form of a step function  
171 (also known as bang-bang control). The step function's threshold is given by  
172  $\tau$  and its height by  $\delta$  (Fig. 1). Thus, an individual  $k$  experiencing a death rate  
173  $d_k$  and having dispersal characters  $(\tau_k, \delta_k)$  will take a dispersal step  $(\Delta x, \Delta y)$   
174 drawn from a Gaussian distribution with mean zero and standard deviation

$$\sigma_d = \begin{cases} 0, & \text{if } d_k < \tau_k \\ \delta_k, & \text{otherwise} \end{cases}. \quad (8)$$

175 The disperser is then given the spatial coordinates  $(x_i + \Delta x, y_i + \Delta y)$ . There-  
176 fore,  $\delta\sqrt{2}$  is the expected (root-mean-square) dispersal distance, given the  
177 decision to disperse.

178 Our model assumes that there is no explicit cost to dispersal. However,  
179 an environmental gradient results in an implicit cost, since individuals run  
180 the risk of moving to a spatial location in which they are poorly adapted.  
181 Increasing the slope of the gradient increases this risk, while decreasing the  
182 slope has the opposite effect.

### 183 *2.5. Boundary Conditions*

184 When a dispersal step would lead outside the unit square, we follow Heinz  
185 et al. (2009) and reset the  $x$ -location to 0 or 1, respectively, and the  $y$ -  
186 location to  $1 + y$  or  $y - 1$ , thus implementing impermeable boundaries in the  
187 direction of the gradient, and periodic boundaries in the ecologically neutral  
188 direction. Competitive interactions stretch across the periodic, but not across  
189 the impermeable boundaries.

### 190 *2.6. Implementation*

191 Time proceeds in increments drawn from an exponential distribution with  
192 mean  $E^{-1}$ . At each time step, either a birth or death event is chosen, with  
193 probabilities  $B/E$  and  $D/E$ , respectively, which makes generations overlap-  
194 ping. After the event type is chosen, individual  $i$  is selected with probability  
195  $b_i/B$  or  $d_i/D$ , respectively. According to the event type, individual  $i$  then  
196 either reproduces or dies. In the latter case, it is removed from the popula-  
197 tion; in the former case, a new individual is introduced into the population

198 as described in Sections 2.3 and 2.4. The theoretical background to this  
199 scheduling procedure is presented in detail by Gillespie (1976).

200 In a population regulated by frequency-dependent competition, as consid-  
201 ered herein, average individual fitness ( $\bar{f}$ ) is zero at equilibrium, and therefore  
202  $\bar{b} = \bar{d} = 1$ . This results in a distribution of environmental cues, more than  
203 99% of which is comprised in the domain  $0.7 \leq d \leq 1.4$  (Fig. 1). Therefore,  
204 in all realizations we initialize the dispersal character  $\tau$  with 0.7, which is  
205 on the fringe of the death-rate distribution, but still under selective pressure  
206 (Fig. 1). Initializing  $\tau$  outside of this range results in virtually vanishing se-  
207 lection pressures on  $\tau$  and thus in the mere genetic drifting of  $\tau$ . Specifically,  
208 if  $\tau$  is initialized well below 0.7, then individuals unconditionally disperse  
209 according to  $\delta$  and all selective pressure falls on  $\delta$ . In this case, our results  
210 reduce to those reported by Heinz et al. (2009). If  $\tau$  is initialized well above  
211 1.4, then individuals never disperse and our results reduce to those of Doe-  
212 beli and Dieckmann (2003) for the case of zero mobility. These two cases  
213 highlight an important aspect of the conditional dispersal function used in  
214 this study: it also allows for unconditional dispersal to evolve.

### 215 *2.6.1. Speciation*

216 In our model, speciation is considered to have occurred when an initially  
217 monomorphic population has split into two or more separate phenotypes.  
218 For asexual populations, we use the term speciation to mean evolutionary  
219 branching, in line with Heinz et al. (2009).

220 We identify speciation as follows (Heinz et al., 2009). For asexual popula-  
221 tions, the initially unimodal phenotype must branch, and remain branched,  
222 into a bi- or multimodal distribution for at least 500 generations. For sexual

Birth rate	$b$	1
Maximal carrying capacity density	$K_0$	300
Standard deviation of carrying capacity density	$\sigma_K$	0.3
Standard deviation of competition function	$\sigma_s$	0.2
Standard deviation of mutation steps	$\sigma_m$	0.001

Table 2: Model parameters and their values, chosen to facilitate direct comparison with Heinz et al. (2009).

223 populations, we additionally demand that virtually no hybrids occur between  
 224 these branches, enforcing the strict requirement that the modes in the phe-  
 225 notype distribution are sharply delineated from one another.

### 226 2.6.2. Parameters

227 The model is described by two dimensionless parameters: the scaled width  
 228 of the phenotypic competition function  $c = \sigma_c/\sigma_K$  and the scaled slope of  
 229 the environmental gradient  $s = a\sigma_s/\sigma_K$ . Here, we systematically vary these  
 230 two parameters in the range  $0.3 \leq c \leq 2.0$  and  $0 \leq s \leq 1$  (as in Heinz et al.  
 231 (2009)), while the numerator of the scaled dispersal distance  $\delta/\sigma_s$  (Doebeli  
 232 and Dieckmann, 2003) is allowed to evolve. The other parameters considered  
 233 in this study are presented in Table 2. For each combination of  $c$  and  $s$ ,  
 234 either 1 or 100 independent realizations were performed, depending on the  
 235 experiment. In each realization, we allow the population to evolve for  $10^5$   
 236 generations and measure the evolutionary dynamics of the phenotypic traits.  
 237 We keep all phenotypic traits in the range  $[0, 1]$ , except for the dispersal  
 238 character  $\tau$ , whose upper limit is left unbounded.

### 239 **3. Results**

240 We begin our analysis with asexual populations, to provide a frame of  
241 reference for the subsequent analysis of sexual populations.

#### 242 *3.1. Asexual Populations*

243 When reproduction is asexual, the joint evolution of the ecological char-  
244 acter  $u$  and the conditional-dispersal character  $(\tau, \delta)$  results in the two qual-  
245 itatively distinct evolutionary outcomes shown in Fig. 2a,b: (i) conditional  
246 dispersal without speciation and (ii) conditional dispersal with speciation.  
247 This occurs under both Gaussian (Fig. 2a) and platykurtic (Fig. 2b) com-  
248 petition, although the parameter region in which speciation does not occur  
249 is slightly enlarged in the platykurtic case.

250 In the first evolutionary regime (Fig. 2a,b, dot symbols), where compe-  
251 tition kernels are wide and environmental gradients are shallow, speciation  
252 does not occur. This result is consistent with Doebeli and Dieckmann (2003),  
253 where speciation is not found under Gaussian competition for  $c \geq 1$  unless  
254 accompanied by steep environmental gradients and low mobility. This ob-  
255 servation also corroborates the results reported by Heinz et al. (2009), who  
256 found that dispersal evolution does not always lead to the reduced mobility  
257 required for speciation.

258 In the second evolutionary regime (Fig. 2a,b, circle symbols), specia-  
259 tion occurs for both shallow environmental gradients accompanied by nar-  
260 row competition kernels and for steep environmental gradients accompanied  
261 by arbitrarily wide competition kernels. This result is again consistent with  
262 Doebeli and Dieckmann (2003), since speciation is expected under Gaussian

263 competition when the gradient is sufficiently steep and/or the competition  
264 kernel is sufficiently narrow ( $c < 1$ ). This is also consistent with the re-  
265 sults reported by Heinz et al. (2009), who furthermore found that increasing  
266 the slope of the gradient led to a marked decrease in the evolved dispersal  
267 distance. Here, we observe a similar trend, but threshold-based conditional  
268 dispersal allows the dispersal distance to remain at relatively high values  
269 even for steep gradients.

270 To illustrate the relationship between conditional dispersal and specia-  
271 tion in asexual populations, we depict in Fig. 3 the evolutionary dynamics  
272 of the ecological character and the conditional dispersal characters under  
273 Gaussian competition, using a parameter combination for which Heinz et al.  
274 (2009) observed short-range dispersal in conjunction with speciation. In Fig.  
275 3a, speciation occurs rapidly, with divergence of the ecological character into  
276 two discrete morphs within 5,000 generations, and into three discrete morphs  
277 within 25,000 generations. In contrast to the case of unconditional disper-  
278 sal studied in Heinz et al. (2009), this happens not through a reduction in  
279 dispersal distance, but rather through an increased reluctance to disperse.  
280 This reluctance is achieved through the evolution of an increased dispersal  
281 threshold (Fig. 3c), which settles around a value slightly greater than the  
282 average death rate. The corresponding dispersal distances drift considerably  
283 during their evolution, but remain consistently and significantly above zero  
284 (Fig. 3b).

285 The evolved conditional dispersal strategy is affected by the steepness  
286 of the environmental gradient (Fig. 4), but is relatively insensitive to the  
287 shape (Gaussian or platykurtic) and the scaled width  $c$  of the competition

288 kernel. (Consequently, in Fig. 4 we present data only for the representative  
289 case  $c = 1$ ). The dispersal threshold  $\tau$  increases with the scaled gradient  
290 slope  $s$  (Fig. 4a), causing an increased reluctance to disperse as the environ-  
291 mental gradient steepens. For shallow gradients, the dispersal threshold  $\tau$   
292 evolves to a value below the population-level average death rate ( $d = 1$ , Fig.  
293 4a, horizontal line), whereas for steep gradients,  $\tau$  evolves to a value above  
294 this average. Thus, when environmental gradients are shallow, dispersal is  
295 selectively favored even in environments where the death rate is below av-  
296 erage. This most likely results from kin competition, as decreased dispersal  
297 increases the spatial clustering of related individuals.

298 For steep environmental gradients, the risk of dispersing to an area in  
299 which the organism is not well adapted is higher than the risk of remain-  
300 ing in an area with above-average death rates; accordingly, higher dispersal  
301 thresholds are selectively favored. The scaled movement distance  $\delta/\sigma_s$  de-  
302 creases with increasing gradient slope  $s$ , since the inherent cost of dispersal  
303 increases with  $s$  (Fig. 4b). The reduction of dispersal distance for steep  
304 gradients was also observed by Heinz et al. (2009). However, the case of  
305 unconditional dispersal considered therein led to dispersal distances evolving  
306 toward zero as the gradient became increasingly steep. Our results demon-  
307 strate that when dispersal is conditional, movement distances always remain  
308 well above zero, regardless of the gradient.

### 309 *3.2. Sexual Populations*

310 In sexual populations, speciation occurs under more restrictive conditions.  
311 Specifically, speciation under Gaussian competition was observed only for  
312 steep gradients and wide competition kernels (Fig. 2c). This result bears a

313 close resemblance to the observations made by Heinz et al. (2009), except that  
314 speciation is now found in conjunction with conditional dispersal, as opposed  
315 to unconditional, short-range dispersal. Under platykurtic competition, the  
316 speciation region dramatically widens toward more intermediate gradients  
317 and narrower competition kernels (Fig. 2d). This result agrees with the  
318 observations made by Leimar et al. (2008) for asexual populations with low  
319 mobility.

320 To illustrate how the speciation process can be frustrated by conditional  
321 dispersal, we depict in Fig. 5 an illustrative example of the evolutionary dy-  
322 namics of the ecological character (Fig. 5a) and the dispersal characters (Fig.  
323 5b,c) using a parameter combination for which speciation was observed in  
324 the case of unconditional dispersal (Heinz et al., 2009). After about 20,000  
325 generations, the population has segregated into three distinct phenotypes  
326 (Fig. 5a). This results from the evolution of the scaled dispersal distance  
327  $\delta/\sigma_s$  (Fig. 5b), which is quickly driven toward zero. Simultaneously, the dis-  
328 persal threshold  $\tau$  (Fig. 5c) evolves toward higher values. As  $\tau$  surpasses the  
329 population-level average death rate at around 40,000 generations (Fig. 5c,  
330 horizontal line), the scaled dispersal distance  $\delta/\sigma_s$  responds with a rapid in-  
331 crease. The resulting conditional dispersal breaks up the discrete phenotypic  
332 clusters that had previously evolved, impeding the evolution of reproductive  
333 isolation (Fig. 5a). In contrast, when dispersal distances evolve toward zero  
334 under unconditional dispersal, phenotypic clusters stabilize and thus result  
335 in parapatric speciation (Heinz et al., 2009).

336 The relationships between the dispersal characters  $\tau$  and  $\delta$  and the scaled  
337 slope of the environmental gradient  $s$  (Fig. 6) are qualitatively similar to

338 the asexual case (Fig. 4), although the scaled dispersal distances  $\delta/\sigma_s$  are  
339 generally higher in the sexual case. In contrast to Heinz et al. (2009), the  
340 evolved mating distances  $w$  (open circles in Fig. 6b) are consistently driven  
341 to small values as  $s$  increases, for all scaled competition widths  $c$ . This is  
342 because non-vanishing dispersal distances make it selectively advantageous  
343 to keep the mate search local, so as to avoid producing maladaptive offspring.

#### 344 4. Discussion

345 Our results demonstrate that the evolution of conditional dispersal has a  
346 significant impact on parapatric speciation along environmental gradients. It  
347 is worth highlighting that even though dispersal evolution may lead to a form  
348 of isolation by distance, the ensuing speciation process remains driven by  
349 frequency-dependent competition, rather than by the gradual accumulation  
350 of reproductive incompatibilities.

351 In asexual populations, speciation can occur for a wide range of parame-  
352 ters, and is always accompanied by conditional dispersal. Both the dispersal  
353 threshold and dispersal distance of the conditional dispersal strategy are in-  
354 fluenced by the steepness of the environmental gradient, with shallow gradi-  
355 ents resulting in lower thresholds and higher dispersal distances, and steeper  
356 gradients resulting in higher thresholds and lower dispersal distances. In  
357 sexual populations, a similar result is obtained for the dispersal thresholds  
358 and distances. However, speciation occurs under a more restricted range of  
359 conditions. Specifically, speciation is only observed when the gradient is suf-  
360 ficiently steep and the competition kernel is sufficiently wide. Enhancing the  
361 disruptiveness of frequency-dependent selection, more box-shaped competi-

362 tion kernels dramatically lower the speciation-enabling slope of the environ-  
363 mental gradient. For species to emerge on more shallow gradients, some form  
364 of assortative mate preference is most likely required, as was found in the  
365 original formulation of this model (Dieckmann and Doebeli, 1999; Doebeli  
366 and Dieckmann, 2003).

367 For well-mixed populations, speciation via frequency-dependent disrupt-  
368 tive selection is facilitated by narrow phenotypic competition kernels (Dieck-  
369 mann and Doebeli, 1999). For populations structured along sufficiently steep  
370 environmental gradients, correlations arise between spatial position and eco-  
371 logical character. Because of the spatial component of the competition kernel  
372 (Eq. 5), an environmental gradient thus induces frequency-dependent dis-  
373 ruptive selection, which therefore occurs even when phenotypic competition  
374 kernels are wide (Doebeli and Dieckmann, 2003).

375 For sexual populations, speciation additionally requires reproductive iso-  
376 lation between phenotypic clusters (which along a gradient tend to corre-  
377 spond to spatial clusters). We only consider isolation by distance; therefore,  
378 for sexual populations speciation becomes easier with increasing spatial dis-  
379 tance between these clusters, and more difficult with decreasing distance be-  
380 tween them. While the distance between clusters is in principle determined  
381 by the width of both the spatial and the phenotypic component of the com-  
382 petition kernel, it is the narrower component that essentially determines this  
383 distance in practice (see also Eq. 5 in Leimar et al. (2008)). Therefore, as the  
384 phenotypic component becomes wide, the distance is mostly defined by the  
385 (fixed) width of the spatial component; however, as it becomes narrow, the  
386 distance between clusters decreases to the point where speciation is hindered

387 by the inability to achieve complete reproductive isolation. In consequence,  
388 narrow phenotypic competition kernels (corresponding to small values of  $c$ )  
389 impede speciation in the sexual case (Fig. 2c,d), but not in the asexual case  
390 (Fig. 2a,b), if isolation by distance is the only isolating mechanism consid-  
391 ered and gradients are not steep enough to limit dispersal. The same trend  
392 was also observed by Heinz et al. (2009).

393 Previous studies of conditional dispersal in metapopulation structures  
394 have observed a reduction in dispersal thresholds in the absence of disper-  
395 sal costs (Travis and Dytham, 1999; Metz and Gyllenberg, 2001). In the  
396 presence of explicit costs, such as increased mortality, the dispersal thresh-  
397 old is often found to equilibrate at the patch carrying capacity (Metz and  
398 Gyllenberg, 2001; Travis et al., 2009). Here, we have found similar results in  
399 populations structured in continuous space and subject to the implicit costs  
400 of an environmental gradient; dispersal thresholds typically evolve toward  
401 values near the population-level average death rate. Whether the dispersal  
402 threshold evolves to a value less than or greater than this population-level  
403 average is directly related to the severity of the cost imposed by the envi-  
404 ronmental gradient and the mode of reproduction, with sexual populations  
405 generally evolving higher dispersal thresholds.

406 The environmental gradient considered in this study influenced the car-  
407 rying capacity experienced by an individual, as a function of the individual's  
408 spatial position and ecological character. In a recent model-based study of  
409 range expansions in metapopulations, Kubisch et al. (2010) demonstrated  
410 that the elasticity of range limits varied between different kinds of environ-  
411 mental gradients. For environmental gradients that affected either dispersal

412 mortality or per capita growth rate, range contractions were observed after  
413 an initial period of expansion. In contrast, when the environmental gradient  
414 impacted patch capacity or patch extinction rate, range contractions were  
415 never observed. These results highlight the potential sensitivity of ecologi-  
416 cal and evolutionary processes to different types of environmental gradients.  
417 How alternative environmental gradients influence dispersal evolution and  
418 speciation in the model investigated herein is an exciting challenge for future  
419 work.

420 We considered impermeable boundary conditions for the spatial dimen-  
421 sion in which the environmental gradient varied. To test the sensitivity of  
422 our results to this assumption, we performed additional experiments in which  
423 competitive interactions are mirrored about the  $x$ -boundary. Such reflective  
424 boundary conditions led to an overall reduction in population size, relative  
425 to the impermeable case, resulting from the now increased competition expe-  
426 rienced at the boundaries. The evolved dispersal thresholds, however, were  
427 indistinguishable between the two boundary conditions. The evolved disper-  
428 sal distances were also indistinguishable for sufficiently steep environmental  
429 gradients, but for shallow gradients, they were lower for reflective boundary  
430 conditions than for impermeable boundary conditions. This is because large  
431 dispersal steps towards the boundaries are favored for the case of imperme-  
432 able boundary conditions, provided the inherent risk of dispersal is low, as  
433 it is on shallow gradients. It is only in this case that the evolved dispersal  
434 distances differ between the two boundary conditions. We also note that  
435 Heinz et al. (2009) found dispersal evolution to be robust to various forms of  
436 boundary conditions.

437 Empirical evidence is still needed to determine the true shape of con-  
438 ditional dispersal strategies in natural populations (Travis et al., 2009). A  
439 variety of functional forms have been considered in theoretical studies of  
440 conditional dispersal (Bach et al., 2007; Kun and Scheuring, 2006; Metz and  
441 Gyllenberg, 2001; Travis and Dytham, 1999), and while these model details  
442 certainly matter (Ronce, 2007), most studies have observed the evolution  
443 of some form of threshold-based strategy. The question addressed here was  
444 not focused on the functional form of conditional dispersal *per se*, but in-  
445 stead on how conditional dispersal, of any form, affects parapatric speciation  
446 driven by frequency-dependent competition along environmental gradients.  
447 Preliminary experimentation with the conditional dispersal functions consid-  
448 ered by Travis and Dytham (1999) and Kun and Scheuring (2006) produced  
449 qualitatively similar results to those reported herein.

450 As discussed by van Baalen and Hochberg (2001), “the ecological and  
451 evolutionary implications of how dispersal may create or destroy biological  
452 patterns are only starting to be appreciated.” Our results contribute to our  
453 understanding of these implications, by demonstrating how both spatial and  
454 phenotypic pattern formation can be generated and subsequently annihilated  
455 by the evolution of conditional dispersal, and how this relates to speciation  
456 processes. These results indicate that the stability of current spatial and  
457 phenotypic distributions should be considered in the context of dispersal  
458 plasticity, as shifts in environmental cues, e.g., such as those expected from  
459 climate change events, may severely disrupt population stability and threaten  
460 biodiversity.

Figure 1: Schematic illustration of four possible conditional dispersal strategies, assumed to take the form of a step function. As a measure of environmental quality, these strategies are conditioned on an individual's death rate  $d$ , and are encoded as a  $(\tau, \delta)$  pair, where  $\tau$  denotes the dispersal threshold and  $\delta$  the dispersal distance (see Eq. 8). The gray bars depict the death-rate distribution of a representative population, illustrating the frequency and domain of experienced environmental cues.

Figure 2: Evolutionary outcomes as a function of the scaled slope of the environmental gradient  $s$  and the scaled competition width  $c$  for (a) asexual populations with Gaussian competition, (b) asexual populations with platykurtic competition, (c) sexual populations with Gaussian competition, and (d) sexual populations with platykurtic competition. In (a) and (c), the lightly shaded region to the right indicates where Heinz et al. (2009) obtained speciation with unconditional dispersal. Whereas in asexual populations, the switch from unconditional to conditional dispersal leads to virtually indistinguishable results, in sexual populations conditional dispersal appreciably reduces the scope for speciation. Small panels on the left illustrate the two different kernel shapes for identical standard deviations.

Figure 3: Evolutionary dynamics of the (a) ecological character  $u$ , (b) scaled dispersal distance  $\delta/\sigma_s$ , and (c) scaled dispersal threshold  $\tau/b$  in asexual populations with Gaussian competition, for a scaled competition width  $c = 2.0$  and a scaled slope of the environmental gradient  $s = 0.6$ . The horizontal line in (c) indicates the average death rate,  $d = 1.0$ .

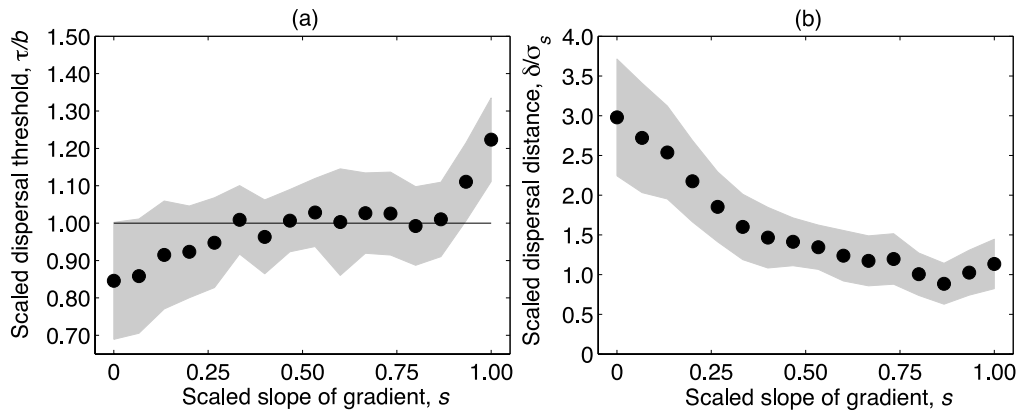

Figure 4: Evolved dispersal strategies in asexual populations with Gaussian competition, shown as a function of the scaled slope of the environmental gradient  $s$ , for the scaled competition width  $c = 1.0$ . The scaled threshold of the dispersal strategy  $\tau/b$  is shown in (a) and the scaled dispersal distance  $\delta/\sigma_s$  is shown in (b). The horizontal line in (a) indicates the average death rate  $d = 1.0$ . Filled circles show the average of the final 5000 generations of 100 independent realizations, and the gray-shaded areas represent the respective standard deviations across realizations.

Figure 5: Evolutionary dynamics of the (a) phenotypic character  $u$ , (b) scaled dispersal distance  $\delta/\sigma_s$ , and (c) scaled dispersal threshold  $\tau/b$  in sexual populations with Gaussian competition, for a scaled competition width  $c = 2.0$ , and a scaled slope of the environmental gradient  $s = 0.6$ . The horizontal line in (c) denotes the average death rate,  $d = 1.0$ .

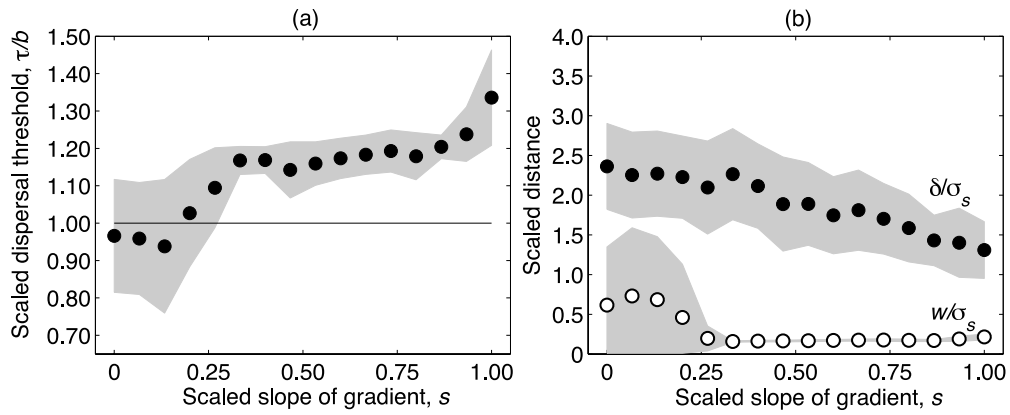

Figure 6: Evolved dispersal and mating strategies in sexual populations with Gaussian competition, shown as a function of the environmental gradient  $s$ , for the scaled competition width  $c = 1.0$ . The scaled threshold of the dispersal strategy  $\tau/b$  is shown in (a) and both the scaled dispersal distance  $\delta/\sigma_s$  and scaled mating distance  $w/\sigma_s$  are shown in (b). The horizontal line in (a) indicates the average death rate,  $d = 1.0$ . Filled circles show the average of the final 5000 generations of 100 independent realizations, and the gray-shaded areas represent the respective standard deviations across realizations.
